Etiology and Pathogenesis. The hermaphroditic adult tapeworm measures about 3 m in length and possesses a globular scolex containing a rostellum with about two dozen hooklets. There are seldom more than a thousand proglottids. The gravid proglottid measures about 6 by 12 mm and contains a uterus with 8 to 12 lateral branchings. The eggs resemble those of *T. saginata*. When ingested by the hog, the embryo is released from the egg, penetrates the intestinal wall, and is carried by vascular channels to all parts of the body. Localization with development to the encysted larval stage, *C. cellulosae* ("bladder worm"), occurs predominantly in striated muscle, particularly that of the tongue, neck, and girdle muscles. The cysticerci are ovoid, gray-white, opalescent structures about 1 cm in diameter. An opaque white spot denotes the site of the scolex. Man becomes infected following ingestion of undercooked pork containing cysticerci. The scolex is freed and attaches itself to the intestinal mucosa, and development to the adult stage begins at this time.

Clinical Manifestations. Clinical manifestations resemble those associated with *T. saginata*. The

manifestations differ when man serves as the intermediate host. This may occur following ingestion of the eggs or the return of gravid segments to the stomach by reverse peristalsis. The released embryo bores into the intestinal wall and is distributed by vascular channels to various parts of the body. Cysticerci develop in the subcutaneous tissues, in muscles, in viscera, and—of most significance—in the eye and brain. Only moderate tissue reaction occurs while the scolex is viable. The dead larva, however, behaves like a foreign body and provokes a marked tissue response. Symptoms are related to active larval encystment only in heavy infections. Muscular pains, weakness, and slight fever may be observed. The involvement in the brain may be in the form of a meningoencephalitis when the cysticerci are widely distributed. However, epilepsy, brain tumor, encephalitis, and other types of neurologic disorder may be simulated. Eosinophilic leukocytosis of the blood and spinal fluid accompanying such clinical manifestations suggests cerebral cysticercosis. Degenerate cysticerci ultimately calcify.

As in other tapeworm infections, a slight to moderate eosinophilia is a fairly constant finding. The finding of eggs in perianal scrapings or in the feces will identify the infection as taeniasis. For a specific diagnosis, proglottids or the scolex must be examined. As in beef tapeworm infection, the diagnosis is usually made by finding proglottids in the feces. Roentgenographic demonstration of calcified foci may aid in diagnosis of cysticercosis. The prognosis is in large part determined by the stage and location of the parasite. Surgery may be indicated in cerebral and ocular cysticercosis.

Treatment. For removal of the worm in the adult stage, see *Taeniasis Saginata*. It is well to administer an antiemetic before giving the Atabrine to prevent reverse peristalsis, with return of the eggs to the stomach and release of the embryos.

Prevention. The simplest and most effective preventive measure is the thorough cooking of pork. Treatment of recognized cases will reduce the hazard of larval stage development as well as the spread of the infection.

Echinococcosis

Definition. Echinococcosis may be caused by the larval stage of *Echinococcus granulosus* or *E. multilocularis*. These species of echinococcus are distinct morphologically and biologically. In man, *E. granulosus* produces cystic, expanding lesions, involving the liver and lungs primarily, whereas the lesions of *E. multilocularis* are destructive because of their invasive character.

Etiology. *Echinococcus granulosus* infection in man, cattle, sheep, horses, and hogs, the principal intermediate hosts, is contracted by ingestion of

the eggs present in the feces of the dog, the principal definitive host. Following ingestion, the embryos escape from the eggs, penetrate the intestinal mucosa, and enter venous and lymphatic channels. Some soon arrive in the liver and may form hydatid cysts there, and those entering the lymphatics are carried ultimately to the lungs. There is no exogenous budding from the wall of the cyst, only endogenous. Transmission to the definitive host occurs following ingestion of the hydatid cysts which contain scoleces. An adult worm may develop from each scolex in the intestine of the dog, wolf, coyote, and other of the Canidae. The adult is small, measuring about 5 mm in length, and consists of no more than 5 or 6 segments. *Echinococcus multilocularis* infection is manifested by the same type of invasive larval-produced lesion as is observed in the natural intermediate host for this stage, the microtine rodents. The adult, or tapeworm, stage is found in the dog and fox.

Distribution. Echinococcosis caused by *E. granulosus* has its highest incidence in sheep- and cattle-raising countries, particularly in North and South Africa, Australia, Central Europe, and South America. In Iceland, a high incidence of infection in man and the dog has been markedly reduced by control measures. In the southern, western, and southwestern areas of the United States, the infection is established, and a small number of cases reported each year. *Echinococcus multilocularis* has been identified in Eurasia, Alaska, and the Kuriles and adjacent islands.

Pathogenesis and Clinical Manifestations. Two principal types of lesions develop in the intermediate host: the unilocular type of *E. granulosus* and the alveolar type of *E. multilocularis*. The former is more common, grows slowly, and consists of an external laminated cuticula and an inner germinal layer. Fluid fills and distends the cyst. Daughter cysts (Fig. 223-3) and brood capsules (Fig. 223-4)

FIG. 223-3. Daughter cysts occur frequently in large old unilocular hydatid cysts. They are thin-walled balloons formed by herniations of the wall of the mother cyst and lie free in the cyst fluid. Free hooklets are also found floating in this fluid. (Ash and Spitz: "Pathology of Tropical Diseases," Philadelphia, W. B. Saunders Company, 1915.)

FIG. 223-4. Brood capsules are vesicles of single-cell layer (A) which arise from the germinal membrane (B). Invaginated scolices (C) arise as buds from the inner surface of the brood capsule. (Ash and Spitz: "Pathology of Tropical Diseases," Philadelphia, W. B. Saunders Company, 1945.)

develop from the germinal layer, representing endogenous development. "Hydatid sand" found in the cyst consists of scolices liberated from ruptured brood capsules. Exogenous development results from evagination of the cyst wall and ultimately produces the multilocular or alveolar type of lesion. Metastatic lesions occur when growth extends into vessels.

Symptoms produced depend upon the size attained by the cystic lesion and the amount of tissue destroyed. Unilocular lesions may become barren following resolution of secondary bacterial infection. Rupture into the peritoneal or pleural cavities may produce an anaphylactoid reaction, which occasionally is fatal. The unilocular type of hepatic lesion progresses slowly and is most amenable to surgical treatment. The alveolar type progresses more rapidly, with metastatic lesions developing in the bones, brain, and other sites. Pathologic fractures occur, and cerebral involvement may be manifested by epilepsy.

Diagnosis and Treatment. Clinical manifestations seldom are characteristic enough to suggest the diagnosis, but roentgenographic appearance of the lesion, especially when calcification is present, is often helpful (Schlanger and Schlanger). Eosinophilia is suggestive, although seldom present. Inquiry should be made concerning residence in an endemic area, and skin (Casoni or substitute antigen) and/or serologic tests performed, before exploration is considered. Exploration may be required as both a diagnostic and a therapeutic measure. Because of serious reactions to the leakage of cyst fluid into the tissues and body cavities, aspiration

should be attempted only during exploration. Aspirated cyst fluid should be examined carefully for scolices, hooklets, and laminated cyst wall. The size of the lesion will determine whether excision or marsupialization is the procedure of choice. Surgical treatment offers the only hope of cure.

Prevention. In prevention, (1) contact with infected dogs should be avoided, particularly fecal contamination of the hands and food; (2) infected carcasses and offal should be burned or buried, in order to prevent access of dogs to material containing scolices; and (3) dogs should be treated if found to be infected. The reduction of the incidence of echinococcosis in Iceland is an example of the efficacy of control measures.

Hymenolepis Nana

Definition. *Hymenolepis nana* is an intestinal infection of man caused by *Hymenolepis nana*, the dwarf tapeworm.

Etiology. The life cycle is unique in that both the larval and adult phases of development occur in the same host. Man, mice, and rats readily contract infection upon ingestion of the eggs. The adult measures about 2 cm in length and may possess over a hundred proglottids.

Distribution. The presence of dwarf tapeworm infection has been reported in temperate and tropical regions around the globe. It is the commonest tapeworm found in the United States, most of the infections occurring in the Southern states.

Clinical Manifestations. This tapeworm infection is characterized by the presence of many adult

worms in the host's intestine. When infection is massive, diarrhea and abdominal pain occur.

Treatment. Atabrine, as prescribed for taeniasis saginata, is moderately effective. Because various stages of the helminth are present simultaneously, it is necessary to repeat the course of Atabrine at least once, after an interval of 2 weeks.

Prevention. This is a difficult problem, similar to that encountered in enterobiasis. Only a single host is involved, and the eggs are immediately infective. Personal hygiene should be stressed. The contamination of food by rats and mice should be prevented.

224 HIRUDINIASIS

Ivan L. Bennett, Jr.

Definition and Etiology. Human hirudiniasis results from the attachment of *Hirudinea* or leeches to the skin or, rarely, to internal mucosal surfaces. Leeches are found in lakes, ponds, and tropical forests and vary in size from a few millimeters to several centimeters in length. They attach themselves firmly to a host and suck blood. Because their salivary secretion contains an anticoagulant, the puncture wounds at the attachment site may continue to bleed freely after the dislodgment of the parasite.

Land leeches are found on bushes in tropical areas of Asia and South America, and man is infected by contact with the foliage. Attachment of aquatic species occurs during swimming or wading in infested waters. Rarely, young leeches may be ingested in drinking water, an event that can lead to serious illness.

Manifestations. External hirudiniasis is painless and is called to the victim's attention by finding the parasites or the bleeding puncture wounds left when the engorged leeches detach. With heavy infestations, significant amounts of blood can be lost.

Internal hirudiniasis results from the attachment of small leeches to the mucosa of the upper respiratory tract, larynx, trachea, or esophagus. Infestation of the vagina, bladder, or urethra has occurred in swimmers. As the leeches engorge and grow, they produce symptoms of obstruction, often with bleeding. Hoarseness, cough, nasal obstruction, dysphagia, nausea, and dysuria are frequent, as are hemoptysis, hematemesis, melena, and hematuria. Anemia may be severe, and death has occurred from obstruction of the epiglottis.

Treatment. Leeches must be removed with care to avoid leaving mouth parts in the wound. Application of a lighted cigarette or vinegar will help with complete removal. Skin wounds should be cleaned and covered; secondary infection is the only complication.

Removal of leeches from the genitourinary tract is facilitated by irrigation. In the respiratory tract, endoscopy and removal are necessary, using topical anesthesia.

Prevention. Use of chemical repellents on skin and clothing and boiling of water are the only measures needed to avoid hirudiniasis.

Section 23: Disorders Caused by Venoms, Bites, and Stings

225 SNAKES AND LIZARDS

Ivan L. Bennett, Jr.

Fewer than one-tenth of the nearly 2,500 known species of snakes are venomous. These poisonous varieties belong to five families or subfamilies: Elapidae (cobras, kraits, coral snakes), found in all parts of the world but Europe; Viperidae (true vipers), found in all parts of the world but the Americas; Hydrophidae (sea snakes); Crotalidae (pit vipers), found in Asia and the Americas; and Colubridae, represented by a few rear-fanged species of Africa. The poisonous varieties of the United States, with the single exception of the coral snake of the Elapidae, are pit vipers and include the rattlesnakes, the water moccasin, and the copperhead. This discussion will center around these species, but the therapeutic measures outlined are applicable to snake bites in all parts of the world.

The number of individuals bitten by poisonous snakes in the United States is estimated at 2,000 to 3,000 per year; deaths are not reported separately but are undoubtedly rare, numbering fewer than 20 per year. In many European countries, deaths from snake bite have averaged only one every 3 to 5 years for the last half-century. In contrast, the estimate of annual deaths from snake bite in Brazil is 2,000 (4 per 100,000 population), and 2,000 in Burma (154 per 100,000).

Etiology. The coral snake is found in the Southern states from Florida to Arizona. It is marked by alternating red and black bands separated by yellow rings. Coral snakes are nocturnal and placid and rarely bite man. The fangs are short and permanently erect; the highly toxic venom is injected

into multiple puncture wounds produced by a series of chewing movements.

The pit vipers are so named because of a small pit between the eye and the nostril. Large venom glands in the temporal region give the head a triangular appearance. They are generally aggressive and likely to strike if disturbed. The fangs are long and hinged, folding posteriorly when the mouth is closed. Pit vipers strike suddenly with a forward thrust of the head, and the instant that the erect fangs make contact, venom is expressed by sudden muscular contraction.

The rattlesnakes, recognized by the horny rattle on the tail which buzzes when the snake is disturbed, are widely distributed. The diamondbacks (*Crotalus adamanteus* in the Southeast and *C. atrox* in the Southwest) are the largest and most dangerous snakes in this country. Others include the prairie rattler (*C. confluentus*), the timber rattler (*C. horridus*), and the pigmy rattlers.

The water moccasin, or cottonmouth (*Agkistrodon piscivorus*), is found in swampy areas or along the banks of streams. It is a strong swimmer and can bite under water. This snake is notorious for inflicting severe facial bites when disturbed in the branches of small trees. The copperhead, or highland moccasin (*A. mokasen*), is a closely related species. Its bite is painful but rarely fatal.

Pathogenesis. Snake Venoms. The venoms of many species have been analyzed; invariably each proves to be a mixture of several toxic proteins and enzymes. As an example, the venom of the Indian cobra (*Naja naja*) contains these distinct and separate substances: a neurotoxin, a hemolysin, a cardiotoxin, a cholinesterase, at least three phosphatases, a nucleotidase, and a potent inhibitor of cytochrome oxidase. Several venoms, including those

of the pit vipers, contain hyaluronidase and numerous proteolytic enzymes. Although opinions differ about the exact role of these components in toxicity, the action of the venom of a given species is usually predominantly *neurotoxic* or *necrotizing*; frequently associated changes are hemolysis and changes in blood coagulation. The venom of elapids, including the coral snake, is *neurotoxic*, and death results from respiratory paralysis, probably caused by damage to brain centers, and a curariform interference with transmission at the neuromuscular junction. The venom of crotalid snakes produces local tissue injury, hemorrhage, and hemolysis; death is preceded by circulatory collapse, the mechanism of which is poorly understood. Systemic absorption of venom occurs through lymphatics, and therapeutic measures designed to reduce lymphatic function are helpful in controlling symptoms. On rare occasions, when venom is discharged directly into a blood vessel, death occurs in less than 10 min.

Factors Affecting Severity. Several factors affect the outcome of snake bite:

1. The age, size, and health of the patient. Envenomation in children is usually serious and a fatal outcome more likely.

2. Bites on extremities or into adipose tissues are less dangerous than those on the trunk or face or penetrating a vessel. A direct stroke of the fangs is more dangerous than a scratch, a glancing blow, or one hitting a bone. The discharge orifice of the fang is well above its tip, and the point of the fang can penetrate the skin without envenomation. Even a thin layer of clothing may afford great protection.

3. The size of the snake, the extent of its anger or fear (if hurt it may inject a large dose of venom), the condition of the venom glands (recently discharged or full), and the condition of the fangs (broken, recently renewed) are all important.

4. The presence of various bacteria in the mouth of the snake or on the skin of the victim (especially clostridia) may lead to serious infection in the necrotic tissues at the local site.

5. Exercise or exertion, such as running, immediately after the bite speeds systemic absorption of toxin.

Manifestations. The bite of a pit viper produces severe pain at the local site within a few minutes. There is rapid swelling; ecchymoses and bullae appear over the involved areas, and as the edema spreads, serosanguineous fluid oozes from the puncture wounds. Systemic effects include circulatory collapse with hypotension, clammy skin, tachycardia, intense thirst, nausea, hematemesis, bloody diarrhea, icterus (rarely intense), hemorrhages from the nose and into the skin, and convulsions. Death may occur after 6 to 48 hr. Survival may be attended by massive local tissue loss from gangrene

and secondary infection; amputation of an extremity is sometimes necessary. Fever with a temperature of 101 to 104°F, polymorphonuclear leukocytosis of 20,000 to 30,000, and albuminuria appear within a few hours in severe cases.

The bite of an elapine snake causes little pain, and local swelling is slight. There are usually multiple fang marks. Numbness and weakness begin in the region of the bite within 10 to 15 min and are followed by ataxia, ptosis, pupillary dilatation and loss of reaction to light and accommodation, palatal and pharyngeal palsies, slurring of speech, salivation, and occasionally, nausea and vomiting. The patient becomes comatose, respirations falter, there are convulsions, and death occurs within 8 to 72 hr.

Treatment. An attempt should be made to determine with certainty that the patient has been bitten by a poisonous snake. Absence of distinct fang punctures and failure of local pain, edema, numbness, or weakness to appear within 20 min are strong evidence against a bite's having been inflicted by a venomous species.

Treatment consists of immobilization, application of a tourniquet, incision and suction, antivenin, refrigeration, measures to combat infection, and general support. All patients should be transported to a hospital as quickly as possible.

Local Measures. A tourniquet should be placed a few centimeters above the bite (if anatomically feasible) and made tight enough to allow one finger to pass beneath it with difficulty. The purpose is to impede lymph flow, and it is not necessary to obstruct venous return; the tourniquet should be loosened and moved proximally when local swelling causes it to tighten. Using whatever antiseptics is available, 1 cm cruciate incisions about 0.5 cm deep should be made through each fang mark and suction applied for at least 30 min. A rubber bulb for this purpose is contained in first-aid kits, but a breast pump, funnel attached to a vacuum line, or heated jar can be used. Mouth suction is permissible if no oral lesions are present. Suction should be carried out for 15 min every hr, then every 2 hr, as long as fluid is obtainable. As the swelling progresses, successive rings of radiating, linear, shallow incisions at the advancing edge of the edema are useful; such cuts will be expanded by the progressive swelling. Once a patient has been hospitalized, a paxev boot is a convenient means of applying suction to an extremity. Extensive or deep slashes over the area are unnecessary. Incision and suction are extremely important and should be carried out diligently in every poisonous snake bite. Antivenin is not a substitute for them and should not be relied on alone.

Immobilization of the affected part during transportation is important in controlling lymph flow; splinting is useful in achieving this. The application

of ice packs to the affected area reduces inflammation and swelling, slows drainage by lymphatics, relieves pain, and curtails local necrosis. Care should be taken to avoid freezing the tissues.

Antivenin. Many of the components of venom are antigenic, and effective antiserum can be prepared by inoculation of horses with graded doses. In this country, the only commercially available antivenin is Antivenin Crotalidae Polyvalent (North and South American Antisnakebite Serum) prepared by Wyeth Laboratories; it is effective against all pit vipers. Kits containing lyophilized antivenin (reconstituted with distilled water to 10 ml per ampul), syringe, normal horse serum for prior sensitivity testing of the patient, and detailed instructions are available. The initial dose for a serious bite should be 5 ampuls intramuscularly and, if antivenin is given within 2 hr after the bite, 10 ml of this can be infiltrated locally. Further antivenin can be given as indicated by progression of swelling or systemic symptoms.

No antivenin for coral snakes is manufactured in the United States, although antiserum is sometimes kept on hand in large zoos. Soro-Anti-Elapidico is the commercial name of an effective serum against coral snake venom that is available from the Instituto Butantan, Caixa Postal 65, São Paulo, Brazil.

The American Association for the Advancement of Science, Symposium on Venoms, listed among the references at the end of this chapter, contains a complete listing of antivenin preparations and their sources throughout the world.

Other Measures. The maintenance of respiration by manual or mechanical aids is important in patients bitten by the elapine snakes. It has been suggested that the cholinesterase of cobra and coral venom is responsible for much of the neurotoxicity and that neostigmine and atropine given as for myasthenia gravis might help. This has not been tested clinically.

Tetanus toxoid or antiserum should be given. If pyogenic infection develops, antibiotics should be used.

Alcohol has no place in the treatment of snake bite. Opiates are contraindicated. Relief of pain with salicylates or Demerol, sedation, maintenance of fluid intake, measures to combat shock, and appropriate management of coma or convulsions are all important.

Limited trials of ACTH and adrenal steroids have not shown any great usefulness of these hormones in lessening local necrosis or systemic intoxication.

Prevention. In snake-infested regions, long trousers, high shoes, boots or leggings, and gloves should be worn. Most important of all is to look where one steps or reaches. A sharp knife or lancet, aquet, suction bulb, and antiseptic suffice for

an emergency kit, and in inaccessible areas, antivenin also should be carried.

Gila Monster Bite

The Gila monsters include the large orange and black lizard (*Heloderma suspectum*) of the arid Southwest and *H. horridum*, a closely related Mexican species. These reptiles are not aggressive, and virtually every instance of their attacking man has involved teasing or handling the animals in captivity. The venom is elaborated in eight glands in the floor of the mouth and secreted directly into the oral cavity, where it bathes the teeth which are grooved posteriorly. The lizard clings tenaciously and is often dislodged only after considerable effort, envenomation occurs by contamination of the wound. The venom contains a potent neurotoxin which is undoubtedly responsible for its lethal effect in experimental animals. Death in man has been reported as occurring within a few hours (in one case, 30 min) after a bite. The venom also produces local tissue injury, excruciating pain, massive edema, and patchy erythema. In recovered cases, acute symptoms have lasted for 3 to 4 days and include nausea, vomiting, hematemesis, blurred vision, dyspnea, dysphonia, and profound weakness. Intense hyperesthesia of the bitten extremity can persist for several weeks. There is no antivenin available. Treatment should consist of tourniquet, incision, suction, measures to prevent or combat infection, including tetanus, and supportive measures. Because Demerol has been shown to potentiate the venom's action in animals, some other analgesic should be used to relieve pain.

226 SPIDERS, SCORPIONS, INSECTS, AND OTHER ARTHROPODS

Ivan L. Bennett, Jr.

The bite of many spiders is locally irritating, and several species can cause severe, even fatal systemic poisoning in man. The most numerous and important of the venomous spiders are the members of the genus *Latrodectus*, widely distributed throughout the world. In the United States and Canada, *L. mactans*, the black widow or "shoe-button" spider, causes nearly all clinically significant arachnidism. In Florida, *L. bishopi*, the red-legged widow spider, has been reported to produce human poisoning resembling mild black widow bite.

The symptomatology and mortality from bites of large, hairy spiders, the tarantulas, such as *Lycosa raptoria* and *Phoneutria fera* in Brazil, *Glyptocranium gasteranthoides* in Peru, and *Loxosceles laeta* in Chile, differ in no important respects from those produced by *Latrodectus* except that there are also likely to be severe necrosis and ulceration locally and hemolysis sometimes occurs.

It is the female *Latrodectus mactans*, the black widow, that bites man. She is glossy black with a body 1 cm in diameter and a leg span of 5 cm. There is a characteristic red "hourglass" mark on the ventral abdomen. She spins her web in wood-piles, sheds, basements, or outdoor privies, is very aggressive, and will bite on slight provocation. The venom is said to be about fifteen times as potent as that of the rattlesnake on a weight-for-weight basis. It produces diffuse central and peripheral nervous excitement, autonomic activity, muscle spasm, hypertension, and vasoconstriction.

In the United States, most spider bites occur between April and October, and many patients are males bitten on the genitalia or buttocks while using a privy. After a momentary sharp pain at the site, there is cramping pain that begins locally within 15 to 60 min and gradually spreads. It can involve all extremities and the trunk. The abdomen is boardlike, and the waves of pain become excruciating, causing the patient to turn, toss, and cry out. Respirations are often labored and grunting. There are also nausea, vomiting, headache, sweating, salivation, hyperactive reflexes, twitching, tremor, paresthesias of hands and feet, and occasionally, systolic hypertension. A mild polymorphonuclear leukocytosis is usual, and many patients have a temperature up to 100°F. After several hours, the pains subside, although mild recurrences for 2 or 3 days are common. It may be a week before well-being is restored. Deaths have occurred, mostly in children and the aged. In an analysis of nearly 1,300 cases from the United States and Can-

ada, the mortality varied from 2.4 to 6.0 per cent. This is higher than is usually stated.

Because the bite itself is not prominent, patients are often thought to have some abdominal catastrophe such as perforated ulcer, pancreatitis, or volvulus. Renal colic, coronary occlusion, tetanus, strychnine poisoning, tabetic crisis, lead colic, and porphyria are other conditions to be ruled out. The abdomen is not tender to palpation in arachnidism, and pains in the extremities are not typical of most of these other disorders.

Treatment. This consists of antiserum and measures to relieve pain. The antiserum is produced in horses by Merck Sharp and Dohme, and a single intramuscular injection of one ampul (2.5 ml) of reconstituted material is all that is needed in most cases; relief is gradual. Hot baths alleviate pain temporarily, and intravenous calcium gluconate or magnesium sulfate will produce dramatic, but usually transient, cessation of cramps. Opiates are sometimes effective. Neostigmine, epinephrine, ACTH, and adrenal steroids have all been reported to give relief in isolated cases and are worth trying.

Scorpion Sting

Scorpions are eight-legged arthropods. Adults are 2 to 20 cm in length. Glands in the terminal segment produce venom, which is injected into the victim by a stinger located on the tip of the tail. Scorpions often enter dwellings. During the day they retreat into crevices; emerging at night, they often get into shoes and clothing and even into bedding. They do not deliberately attack man, but accidental contact results in a sting.

Of about 650 species, roughly 40 occur in the United States, distributed over three-fourths of the nation. They are most numerous in the South from Florida to California, but the only two lethal species, *Centruroides sculpturatus* and *C. gertschi*, are limited to Arizona and portions of neighboring states. In general, scorpions are not encountered in New England and the Great Lakes area.

The venom is neurotoxic. It acts locally upon sensory nerves and centrally upon the medulla and involuntary nervous system causing circulatory, respiratory, and widespread autonomic disturbances.

Dangerous species found in the United States, *C. sculpturatus* and *C. gertschi*, reach a maximal length of about 7 cm. Their sting may be fatal to young children or old people, but seldom to a healthy adult. In the years 1929 to 1948, there were 68 deaths from scorpion sting reported from the state of Arizona.

Most of the nonlethal species of scorpions in the United States cause only minor reactions, like a bee sting. Some in the Southwest, however, produce local edema and ecchymosis, with burning pain. In contrast, many species whose venom has potentially

dangerous systemic effects, including the Arizona *Centruroides*, evoke little or no visible reaction at the site of the sting. There is an immediate burning sensation followed by local paresthesia ("pins and needles"), hyperesthesia, or numbness. These spread to involve the whole extremity, and within an hour or two, malaise, restlessness, lacrimation, rhinorrhea, salivation, perspiration, nausea, and vomiting appear. The emeses may contain blood. Transient hypertension, glucosuria, and premature ventricular contractions have been recorded. In fatal cases, dyspnea may occur without cyanosis. Tachycardia with muffled heart sounds and feeble pulse may be noted, or there may be bradycardia and respiratory depression, with irregular or Cheyne-Stokes breathing. Pulmonary edema develops terminally. The patient passes from an agitated state with hyperactive reflexes into coma; convulsions follow. Death usually occurs within 12 hr, but sometimes as late as 2 days after the sting.

Treatment. This consists of immediately placing a tight ligature on the extremity just proximal to the sting, followed by application of ice and, as soon as possible, immersion of the involved member above the ligature in ice water. The ligature must be removed in 5 to 10 min, but the limb is kept refrigerated for at least 2 hr. After this time, if treatment has been applied promptly, it is said that no serious effects are experienced following the sting of *C. sculpturatus* or *C. gertschi*. If the sting is on the head, trunk, or genitalia, of course, the ligature cannot be used, but the area may be chilled with an ice pack.

Other authors recommend tourniquet, incision, and suction as in the treatment of snake bite. However, the amount of venom is minute; it produces no local necrotizing effect and is absorbed so rapidly that unless these procedures are carried out very promptly they are of doubtful value.

Supportive therapy is directed at combating shock and dehydration. Barbiturates in large doses are useful in reducing restlessness.

Prevention. This depends upon alertness in avoiding contact with scorpions in infested areas. Clothing and shoes should be well shaken before being put on in the morning. Towels and bedclothes should be inspected. A house infested with scorpions can in time be rid of them by closing all obvious ways of ingress, picking up debris in the environment, such as piles of brush, logs, stones; introducing a mixture of fuel oil or kerosene, containing a small amount of creosote, between the earth and the house foundation; and spraying with a mixture of 2 per cent chlordane, 10 per cent DDT, and 0.2 per cent pyrethrins in an oil spray base. The spray is applied in a band 3 ft wide to the outer walls, to the undersurface of the house, also to screens and crevices around windows and

plumbing, and under the eaves. Inside the house, the attic, woodwork, plumbing, cupboard, and closet interiors are similarly coated with the residual spray, which under protected conditions has proved effective for as long as 6 months.

Bees, Wasps, and Ants

Bee or wasp venom is hemolytic and neurotoxic and has a histamine-like action. Multiple stings in man cause pain and discomfort, but only in enormous numbers (500 to 1,000) can they cause death. Apiarists become immune to the venom and can sustain many stings without effect.

The usual reaction to a single bee or wasp sting is sharp pain, local wheal and erythema, intense itching, and, in loose tissues such as the eyelid or genitalia, considerable local edema. This subsides in a few hours. Only in the rare case when a bee is inhaled or swallowed and edema of the laryngopharynx or glottis develops is there danger. A sting directly into a peripheral nerve may destroy its function for a time, much as does an injection of alcohol. There have, for example, been cases of Bell's palsy following sting into the trunk of the facial nerve.

In hypersensitive individuals, a single sting may produce serious anaphylaxis with urticaria, nausea, abdominal cramps, asthma, massive edema of the face and glottis, dyspnea, cyanosis, hypotension, coma, and death. Sensitization is usually a result of previous stings; beekeepers sometimes develop allergic rhinitis followed by asthma when near bees or objects that have been in contact with bees. These individuals are likely to have serious reactions to a sting.

Many ants can produce stinging bites with local redness and swelling, including the notorious "fire ant" whose bite can result in vesiculation.

The usual sting is treated by local cool applications and antipruritic lotions or oral antihistaminics. Epinephrine, 0.3 to 0.5 ml of 1:1,000 aqueous solution subcutaneously, repeated every 20 to 30 min, may be lifesaving in patients allergic to bees and/or wasps. This drug can be given as 1:100 solution in oil intramuscularly. Oxygen, antihistaminic drugs, and other supportive measures should be used. Desensitization by injections of extracts of whole bees and wasps has been reported but if this is not practical, contact with these insects should be avoided and, if exposure seems likely, epinephrine or sublingual Isuprel tablets should be kept on hand.

Tick Bite and Tick Paralysis

The local reaction to the bite of a tick may be nothing more than an itching papule which subsides within a few days unless there is secondary bacterial infection. However, incomplete removal

of a tick, with retention of the mouth parts can result in the local formation of a nodule which continues to grow and is sometimes annoyingly pruritic. The definitive treatment is surgical excision of the nodule. Histologically, the nodule is a granuloma, but the inflammatory response is sometimes so bizarre and changes in the overlying epithelium so striking that, in the absence of a history of tick bite, a mistaken diagnosis of malignant tumor has been made.

Removal of a tick by steady pulling is preferable to crushing. Touching with a glowing cigarette, freezing, or application of a drop of oil facilitates removal without leaving embedded remnants.

Tick Paralysis. Tick paralysis is a reversible disorder of the nervous system which sometimes develops in the host while a tick is engorging. It may occur in man or animals. The disease has been reported from many countries. It has long been recognized in the northwestern United States and western Canada, where the wood tick, *Dermacentor andersoni* Stiles, is responsible. More recently the dog tick, *D. variabilis* Say, has been identified in a number of cases occurring in the Eastern states. *Amblyomma americanum*, the lone star tick, and *A. maculatum*, the Gulf Coast tick, have also been incriminated.

While engorging, the tick apparently injects a neurotoxin which acts upon the spinal cord and bulbar nuclei, causing incoordination, weakness, and paralysis. It has been shown in animals that there is failure of neuromuscular transmission and striking impairment of stretch reflexes. The toxin is rapidly destroyed or excreted, for when the tick is removed the nerve cells soon regain normal function.

Tick paralysis has been produced in experimental animals only with gravid female ticks, suggesting that the toxin might be elaborated by the ova. However, injection of extracts prepared from tick eggs has failed to reproduce the clinical picture in convincing fashion.

The tick must feed for several days before symptoms develop. Female ticks commonly remain attached for 7 to 9 days or longer. Paralysis is seen in experimental animals after 5 to 7 days of engorgement. Male ticks feed for a shorter period, a fact which may explain why they are less likely to cause paralysis.

Experimental confirmation of the theory that the toxin is produced in tick salivary glands is also lacking. It has been found that not all gravid female ticks of incriminated species cause paralysis. The nature, site of production, and mode of action of the toxin have not been established.

Most human cases occur in children, generally in young girls. The tick is usually attached to the scalp and hidden by the hair, but may be found on

any part of the body, especially the ear, axilla, groin, vulva, or popliteal region. Both white and Negro races are susceptible.

The patient may be irritable for 24 hr before motor involvement appears. Mild diarrhea may occur. There is weakness and poor control of the legs. The tendon reflexes in the legs are diminished or absent, and the Romberg sign is positive. Temporary improvement may occur, and if the tick is removed at this stage, true paralysis may never develop. Otherwise the symptoms recur within 24 hr, with flaccid paralysis which extends in one or more days to involve the trunk, arms, neck, tongue, and pharynx. Sensory changes are usually absent, but there may be paresthesia and hyperesthesia in the affected extremities. Nystagmus, strabismus, and facial paralysis are sometimes noted. The respirations become shallow, rapid, and finally irregular. The patient sinks into stupor, cyanosis appears, and death results from respiratory paralysis or from obstruction of the airway by aspirated material.

There is little or no fever unless a secondary infection is present. The leukocyte count is usually not elevated, but moderate leukocytosis may occur. The spinal fluid is almost always normal.

Tick paralysis is apt to be confused with poliomyelitis, the more so because ticks are active in warm weather when poliomyelitis is most prevalent. In tick paralysis, however, there is usually no fever and the spinal fluid is normal. Muscle spasm and stiffness of the neck and back are minimal or absent. Ataxia, sometimes with paresthesia, often precedes paralysis by hours or days, first in the legs, then in the arms. Ascending involvement is characteristic, whereas progression of paralysis without fever is exceptional in poliomyelitis.

Among other diseases which might be considered in differential diagnosis are polyneuropathy, transverse myelitis, infectious neuronitis (Guillain-Barré syndrome), syringomyelia, and spinal cord tumor.

Definitive treatment is removal of the tick. Mouth parts retained in the skin should be promptly excised. The patient's body should be searched for other ticks. There is striking improvement within a few hours after removal.

If the tick is removed before bulbar involvement develops, the paralysis subsides, and recovery is complete in a few days, sometimes within 24 hr. The patient should be observed until the recovery trend is established, because if other ticks or retained mouth parts have been overlooked, the paralysis may progress. When bulbar or respiratory paralysis is present, death may occur if the tick is not removed in time. Other treatment is supportive.

Other Arthropods

Flea Bite. There are many fleas that attack man, including *Pulex irritans*, and chicken fleas. In sen-

sitive individuals, the salivary secretion of these bloodsuckers produces large, itching papules. Treatment is symptomatic only. Elimination of fleas in an environment may be very difficult, but persistent treatment of animals and of premises with appropriate insecticides is usually successful.

Centipede Bite. Local irritation is the usual reaction to centipede venom, although extensive necrosis and systemic illness have followed severe poisoning by tropical species. Treatment is purely symptomatic.

Caterpillar Urticaria. Contact with hairy caterpillars of many species produces irritation of skin or mucous membranes. The type of venom involved is not known but severe pain, erythema, urticaria, and even blister formation can come on rapidly after direct contact with caterpillars, after handling cocoons, or on being exposed to windblown fuzz. There is often a regional lymphangitis and transient eosinophilic leukocytosis. The discomfort subsides within 24 hr, but local soaks, oral antihistaminics, and where pain is severe, oral codeine are often indicated.

Bedbug Bite. Members of the genus *Cimex* inflict bites that leave reactions varying from a simple puncture to large urticarial lesions, apparently depending upon the sensitivity of the bitten individual. There is no specific treatment.

Chiggers or Redbugs. These are tiny mites which are commonly found in foliage, grass, etc., in many parts of the world. In the United States, the larval form of *Eutrochilula alfreddugesi* attacks the skin by secreting a substance which digests tissue, creating a red papule that itches intensely. The tiny reddish larva can be seen in the center of the lesion. Treatment is palliative with antipruritic applications. There is no better example of the virtues of prevention than this annoying affliction. The use of insect repellents, appropriate protective clothing, and prompt bathing after exposure reduce the risk of infestation considerably.

Myiasis. There are, generally speaking, three ways in which human tissues may become infested by maggots. Species of flies which usually deposit eggs in carrion, feces, or garbage may lay eggs in an open wound or ulcer, usually a lesion that is necrotic and suppurating. When the larvae hatch, they feed upon the dead tissue, and despite the unesthetic aspects, the deliberate introduction of maggots has been used to supplement surgical debridement.

Occasionally, food containing fly eggs will be ingested, and when the larvae hatch, *intestinal myiasis* can result in nausea, cramps, and diarrhea. The larvae are passed in the feces.

Finally the larvae of many flies, including the sheep fly and horse fly, will attack living, viable tissue. If eggs are laid in the eyes, nose, ears,

mouth, or vagina, an event that usually occurs in sleeping infants, the larvae hatch out and can produce extensive destructive lesions; indeed fatalities have been reported.

The treatment for maggot infestation is surgical removal by irrigation and mechanical extraction. Obviously, control of fly populations by appropriate sanitary precautions is the important step in prevention. Protection of infants by screening and of wounds by bandaging is indicated in infested areas.

227 MARINE ANIMALS

Ivan L. Bennett, Jr.

The elaboration of substances that are poisonous for man is by no means an exclusive property of reptiles and arthropods. Several plant and animal products that are toxic when ingested are described in Chap. 103 (p. 815). In this chapter, discussion will center around venoms of marine animals known definitely to cause illness in man after injection or inoculation under naturally occurring conditions. Information about these toxins is limited, a few isolated clinical observations being the only data available about some of them. An excellent compilation and bibliography will be found in the review by Halstead listed at the end of the chapter.

Sea Anemone Sting (Sponge Diver's Disease). Contact with certain sea anemones (especially *Sargatia elegans*) in Mediterranean and African waters produces extensive dermatitis with chronic ulceration. Occasionally, especially during August and September, systemic symptoms of headache, sneezing, nausea, chills, fever, and collapse are noted. Rare fatalities have occurred. No specific therapy is known, the skin lesions have been thought to benefit from local x-ray irradiation. The disease confers no immunity.

Sponge Poisoning. Direct contact with several species of sponge results in a painful dermatitis. It is known that extracts of the sponges are lethal for mice. Dilute acetic acid ameliorates local pain strikingly and alkali will intensify it. The lesions are self-limited.

Portuguese Man-o-War and Jellyfish Stings. The burning discomfort induced by contact with "sea nettles" or jellyfish is familiar to most surf bathers. Contact with the tentacles of the colorful Portuguese man-o-war (*Physalia* species) or more toxic jellyfish (*Chiropsalmus* of the Indian Ocean and *Rhizostoma* of the Atlantic) is followed by severe pain, swelling, and erythema. Muscle pain, weakness, abdominal cramps, nausea, dyspnea, cyanosis, and collapse may persist for several days, and

fatalities have occurred, sometimes within hours after contact.

Treatment consists of local application of ammonia, alcohol, or calamine, oral or parenteral antihistaminics, and systemic support. Cortisone has been thought to help in a few cases.

Cone Shell Poisoning. The colorful cone shells are highly prized by collectors. Many species in the Pacific are venomous, a great danger to unwary hobbyists who pick them up. The poison is delivered into a wound inflicted by pointed hollow teeth resembling darts in the long proboscis of the animal. Local manifestations include sudden intense pain, swelling, and cyanosis followed by numbness. The venom is apparently a neurotoxin and produces muscular incoordination, weakness, confusion, tachycardia, and dyspnea. Death can occur within 3 to 5 hr, but recovery within 24 hr is the rule. Recommended treatment is the use of tourniquet, incision, and suction (as for snake bite) and supportive measures which may include artificial respiration and oxygen.

Sea Urchin Sting. Contact with the spines of some species of sea urchin results in painful erythema and ulceration with or without neurotoxic symptoms of weakness and frank paralysis of lips, tongue, and face lasting for several hours. Treatment is purely symptomatic and supportive. The toxins isolated from sea urchins have produced paralysis in animals and are notably resistant to heat. Deaths from paralysis and drowning have been reported.

Fish Stings. The dorsal fins or spines of bullhead sharks, dogfish (the familiar *Squalus acanthias* of biology classes), and ratfish and the dorsal and other fins of the scorpion fish, weeverfish, toadfish, and catfish are grooved and at their bases are found venom glands. Injury by these spines results in severe pain and swelling and, in some instances, neurotoxic manifestations. Local gangrene with extensive tissue loss is a complication of catfish stings that may prolong convalescence. Little or nothing is known of the venoms involved. Suction and hot applications are advocated immediately after injury. Tetanus toxoid or antitoxin should be given also. Narcotics are often required to control the pain. Secondary pyogenic infection is a frequent complication to be watched for and managed appropriately.

Probably the most frequent type of venomous fish injury in this country is that produced by the lashing tail of the stingray of the California coast (*Urolophus halleri*). The bony spine is encased in a sheath of epithelial cells containing venom which is expressed into the puncture wound. The wound may be several centimeters deep, portions of the bony spine may break off in it or, more often, the integumentary sheath remains in the wound.

The venom is a circulatory depressant in animals, but local injury predominates in man. There is immediately severe pain and cyanosis followed by erythema and edema. Weakness, rarely, convulsions, and death can ensue. Treatment consists of application of a tourniquet (the vast majority of these injuries occur on the legs) and copious syringing of the wound with salt water to remove fragments of sheath followed by immersion in water as hot as the patient can stand for 1 hr. The venom is heat-labile, and extensive trials have indicated the usefulness of this last procedure. Tetanus toxoid or antiserum is indicated and, as

with other fish stings, pyogenic infection is a frequent complication.

Section 24: Diseases of Uncertain Etiology

228 SARCOIDOSIS

Ivan L. Bennett, Jr.

Definition. Sarcoidosis (Besnier-Beck-Schaumann disease) is a granulomatous inflammatory disease of uncertain etiology. The typical lesions, so-called hard tubercles, are distributed systemically, involving particularly lymph nodes, lungs, skin, liver, spleen, bones, eyes, heart, and skeletal muscle. Other manifestations include hyperglobulinemia, cutaneous anergy, and hypercalcuria, the last associated in many cases with renal insufficiency. The course may be chronic with intermittent disability depending upon the organs involved, there may be eventual complete clearing, or the disease may progress steadily to a fatal outcome.

Etiology. The etiology of sarcoidosis is a complete mystery. Suggestions have included atypical tuberculosis, infection by various viruses and fungi, exposure to beryllium, silica, etc., and sensitization to pine pollen. None of these is supported by firm evidence. The histologic similarity of sarcoid and several other specific or nonspecific granulomatous diseases has given rise to the suggestion that sarcoidosis is a tissue reaction that can be evoked by noxious stimuli of several types. This is nothing more than speculation.

Epidemiology. Sarcoidosis occurs all over the world, but the vast majority of cases have been observed in Great Britain, Scandinavia, Germany, Switzerland, France, and the United States, a situation that may change as the disease is recognized elsewhere. The peak incidence comes between twenty and forty years of age, and there is no sex predominance. Careful epidemiologic studies have shown a clear predilection for rural dwellers, and

most striking of all, the disease is at least fifteen times as common in Negroes as it is in whites in the United States. Although sarcoidosis has been observed occasionally in identical twins and in siblings, there is little to indicate that it is transmitted from patient to patient by contact.

Pathology. The characteristic lesion is the hard tubercle consisting of compact clusters of epithelioid cells. These heal by fibrosis, leaving hyaline scars. Tubercles often coalesce, and giant cells are usually evident. These cells are frequently seen to contain laminated "Schaumann" bodies or stellate "asteroid" bodies, inclusions that are by no means pathognomonic of sarcoidosis although they are far more frequent in the lesions of this disease than any other. It is most unusual to see lymphocytes in appreciable numbers associated with hard tubercles, and caseation is not a feature of sarcoidosis. Fibrinoid necrosis of the centers of hard tubercles is sometimes observed, but this is never extensive and it incites little or no secondary inflammatory response.

It must be emphasized that these histologic changes are not pathognomonic of sarcoidosis although they are characteristic enough that biopsy examination will confirm the diagnosis in the presence of appropriate clinical findings. Exposure to beryllium and silica and the presence in the lesion of tubercle bacilli or fungi must always be excluded.

Active lesions produce symptoms by displacement of or encroachment upon normal structures, and with healing there may be permanent distortion by

Manifestations. Because sarcoidosis can involve almost any tissue, the symptoms and signs are extremely variable. Constitutional symptoms of mild fever, weight loss, etc., are present in many cases

and progress insidiously without localizing complaints or signs.

The lungs are very frequently involved. Often, the first indication of the disease is the detection of pulmonary lesions by routine chest x-ray. The changes are extremely variable, including diffuse reticular or miliary infiltrates, large nodules, or multiple "soft" lesions; bilateral symmetry is the rule. Mediastinal lymphadenopathy is frequent and sometimes massive, so-called "potato nodes" are seen. Enlargement of the right paratracheal nodes is very common, but this finding is by no means so characteristic of sarcoidosis as has been stated in the past.

Dyspnea with progressive disability is sometimes a presenting complaint, but generally, symptoms are milder than would be expected from the extent of x-ray changes. The functional alterations produced by pulmonary sarcoidosis are discussed in detail on p. 1527.

In a few patients, sarcoidosis begins abruptly with the onset of *uveoparotid fever* (Heerfordt's syndrome). There are high fever, swelling of the parotid and lacrimal glands (usually painless), granulomatous uveitis (see p. 423), and cranial nerve palsies, the facial nerve being by far the most frequently involved. This illness subsides spontaneously after a few weeks; the only residual is often incomplete clearing of the ocular lesion.

Generalized lymphadenopathy is common. However, tubercles are found with great frequency in nodes that are only slightly enlarged, and in seeking to confirm the diagnosis, biopsy examination of any palpable lymph node is well worthwhile.

From 20 to 40 per cent of patients develop *cutaneous nodules, papules, or plaques* containing hard tubercles. Because the skin lesions are so variable in their gross appearance, biopsy of any dermatologic abnormality should be carried out when sarcoidosis is suspected. *Erythema nodosum* with arthralgia, fever, and hilar adenopathy is particularly common in females at the onset of sarcoidosis. Usually, these patients do not go on to chronic disability and become free of the disease within 2 years. Interestingly enough, patients who show hilar adenopathy without *erythema nodosum* are far more likely to develop chronic, progressive sarcoidosis.

Granulomatous uveitis, usually bilateral, occurs in many patients with sarcoidosis and may leave residual visual impairment because of corneal or lenticular opacities or glaucoma. Chronic enlargement of the lacrimal glands is seen with considerable frequency.

The heart is sometimes involved by sarcoid tubercles, leading to arrhythmias, conduction defects, or very rarely, myocardial insufficiency with congestive heart failure.

The liver contains hard tubercles in about three-fourths of all cases, although it is unusual for this to result in any symptoms. Hepatomegaly is detectable in 25 per cent of patients, but jaundice or significant alterations of liver function are exceptional.

Splenomegaly is frequent at autopsy, and the spleen can be palpated in about 25 per cent of cases. Occasionally, sarcoidosis is accompanied by *thrombocytopenic purpura* or *hemolytic anemia*, disorders that are usually alleviated by splenectomy.

Bone involvement occurs most frequently in patients with cutaneous sarcoidosis. Radiologically, punched-out lesions of the terminal phalanges or more diffuse resorption of medullary bone with trabecular reticulation are the two most typical patterns observed.

It is often stated that sarcoidosis does not involve the joints. However, several instances of *acute polyarthritis* as a presenting manifestation of the disease are on record, and the presence of hard tubercles in the synovial tissues has been confirmed by biopsy. Some of these patients were thought initially to have rheumatoid arthritis.

The nervous system is affected in occasional patients. The cranial palsies associated with *uveoparotid fever* have been mentioned. Encephalitis, meningism, convulsions, diabetes insipidus, and expanding lesions of the spinal cord are rare, but all have been observed and confirmed as resulting from sarcoidosis.

Renal failure is rarely a result of direct involvement of the kidneys by hard tubercles. However, many patients with sarcoidosis have hypercalcemia with or without hypercalcemia, and this results in impairment of kidney function, nephrocalcinosis, or the formation of renal calculi. There is increased absorption of calcium from the intestine in these cases, resembling increased sensitivity to vitamin D or the activity of some endogenous substance with activity similar to that of vitamin D.

Laboratory Findings. Mild anemia is frequent, and the sedimentation rate is usually elevated. Hemolytic anemia and thrombocytopenia have been mentioned elsewhere. A few patients show mild eosinophilia, but this is not helpful in diagnosis. Hypercalcemia and hypercalcuria have already been discussed. Serum phosphorus is usually normal. Hyperglobulinemia is present in a majority of patients, usually a result of increase in γ and α_2 fractions. Occasionally, the serum alkaline phosphatase will be strikingly elevated in the absence of demonstrable bony involvement.

X-ray changes in the lungs and phalanges have been described already, and the electrocardiogram will sometimes show arrhythmias, conduction defects, or the changes of *cor pulmonale*.

About 85 per cent of patients with sarcoidosis fail to react to intracutaneous tuberculin. However,

this anergy extends to other protein antigens and is in no way diagnostic.

The so-called Kveim reaction is elicited by intracutaneous injection of a 10 per cent suspension of lymph node tissue obtained from a patient with sarcoidosis. After 1 month or more, a small nodule will appear at the injection site. If, on biopsy, this contains hard tubercles, the test is positive. Despite lack of a standard antigen and occasional difficulties in interpreting the test, the Kveim reaction is a valuable diagnostic aid. It is positive in 60 to 80 per cent of cases of sarcoidosis.

Diagnosis. In the presence of pulmonary lesions, hilar and general lymphadenopathy, uveoparotid fever, skin lesions, hypercalcemia, erythema nodosum, rheumatoid-like arthritis, granulomatous uveitis, or combinations of these manifestations, sarcoidosis should be suspected. Confirmation by biopsy of lung (rarely indicated), scalene or other lymph node, skin, liver, skeletal muscle (a surprisingly frequent source of hard tubercles) or synovium should be attempted.

Other situations in which sarcoidosis should be considered are thrombocytopenic purpura, hemolytic anemia, diabetes insipidus, unexplained renal failure, arrhythmias or heart block, and unexplained myocardial insufficiency.

Complications. Other than the many types of functional impairment already mentioned, infection is the only significant complication. *Tuberculosis* and *cryptococcosis* are more likely to occur in patients with sarcoidosis than in the general population and should be watched for carefully.

Treatment. Many patients with sarcoidosis are asymptomatic and require no therapy at all. The only agents that have any effect upon the lesions are the adrenal steroids and ACTH. Steroid therapy is indicated in patients with pulmonary, cardiac, or renal insufficiency, nervous system involvement, hypercalcemia, and active ocular disease as well as rapidly spreading lesions in the absence of specific disability.

A dose of 25 to 40 mg prednisolone daily or the equivalent of another steroid should be given. Response is slow and may not be evident for 3 to 6 weeks. Steroids should not be abandoned as ineffective until a trial of at least 8 to 12 weeks has been completed. If symptoms subside, dosage should be reduced gradually until a maintenance level is found. Patients should be continued on steroids indefinitely, with periodic attempts to reduce dosage or to discontinue the drug entirely.

Prognosis. The mortality in sarcoidosis is low, probably about 5 per cent. Residual disability is entirely dependent upon the sites involved and the amount of irreversible functional loss attributable to fibrosis. The most frequent cause of death is cor pulmonale secondary to pulmonary insufficiency.

With steroid therapy, patients are certainly better assured of comfort and activity, but it cannot yet be said that mortality or length of life have been affected by hormonal treatment.

229 INFECTIOUS MONONUCLEOSIS

M. M. Wintrobe

Definition. This disorder is of unknown etiology, usually benign and probably of infectious origin, which is characterized by irregular fever, sore throat, lymphadenopathy, and enlargement of the spleen, as well as by an absolute lymphocytosis made up of cells of a peculiar type. High concentrations of antibodies against sheep erythrocytes are demonstrable in the blood serum.

History. Since the designation "infectious mononucleosis" was first proposed by Sprunt and Evans in 1920, an ever-increasing number of cases has been observed and reported, especially since 1935. This is due, at least in part, to better recognition of the disease. Prior to 1920 a few sporadic cases had been observed. The relationship of epidemics in children and in adults described under the title of "glandular fever" to infectious mononucleosis is in doubt because in most instances appropriate serologic techniques were not used, and when they were, the results were indefinite and irregular.

Etiology and Pathogenesis. This is a disease of young people, including children, which has now been observed practically throughout the world. In the United States, infectious mononucleosis has been less frequent in Negroes than in white per-

sons. It is a relatively common condition in interns, medical students, and nurses, but many cases among other persons undoubtedly pass unnoticed. The mild or nonspecific character of many of the symptoms may be responsible, or the fact that appropriate blood examinations have not been made. With increasing frequency, sporadic cases have been observed wherever young people live together, as in boarding schools, colleges, and military groups. Infectious mononucleosis is quite uncommon over the age of forty but has been encountered occasionally.

The etiology is unknown, although it is generally believed that the disease is infectious in nature. It is likely that individual susceptibility is low and that the causative agent is extremely labile. It has been stated that it is acquired by the intimate oral exchange of saliva. No clear instances of successful experimental transmission to human subjects have been reported and, in the main, experiments both in man and in animals have yielded little knowledge as to the nature of the causative agent.

Clinical Picture. In the absence of a demonstrable etiologic agent, some have assumed that the clinical manifestations of infectious mononucleosis are protean and have been willing to include under this diagnosis many cases of otherwise unexplained, self-limited febrile disorders with clinical and hematologic features somewhat resembling those of infectious mononucleosis, especially when occurring in young persons. Such a comprehensive approach does not seem to be justified. For the present, at least, it would seem better to restrict the diagnosis to cases in which the lymphocytes constitute more than 50 per cent of the leukocytes, "atypical" lymphocytes are present, and both of these features have been present for a period of at least 10 days. In addition, the titer of heterophil antibodies, after guinea pig absorption, should be at least 1:28. The clinical picture of the disorder, so defined, is quite a consistent one.

Three clinical stages can be identified, namely, (1) a prodromal period of 3 to 6 days, characterized by nonspecific features similar to those of other infections and during which diagnosis may be difficult; (2) a mid-stage of 4 to 20 days during which the full-blown disease presents itself; and (3) the stage of convalescence.

The incubation period is uncertain and may be as long as 4 to 7 weeks. The onset is gradual, but ultimately bilateral lymph node enlargement develops in practically all cases. The cervical glands are always affected, the axillary and inguinal frequently but not invariably. The glands are affected singly or in groups. Local heat, redness, or marked tenderness of the glands are conspicuously absent. The spleen is enlarged in at least 50 per cent of cases.

The most common syndrome is the pharyngeal (80 per cent of cases). Pharyngeal inflammation varies in intensity, but hyperplasia of pharyngeal lymphoid tissue is almost always present. The palatal arch and uvula often have a gelatinous appearance, but significant edema of the uvula is unusual. In some cases the throat presents the typical picture of follicular tonsillitis or that of Vincent's angina or of diphtheria. Stomatitis may be present.

The fever is of no characteristic type. It may be transient in degree, but in one-sixth to one-third of cases the temperature reaches a peak of 103 to 104°F, only occasionally higher. The temperature may rise in a remittent manner in the course of 4 to 8 days. A secondary rise after an initial drop to normal may accompany the onset of glandular swelling or sore throat.

A typhoidal syndrome, with fever, malaise, and headache predominating, is seen in 12 per cent of cases. The headache may be so severe as to suggest meningitis. Gastrointestinal symptoms are rare.

In about 8 per cent of cases icterus occurs and the picture of hepatitis is found. In the majority of cases, however, hepatitis without jaundice is present, as judged by liver function tests. The hepatic disease is usually mild.

Edema of the eyelids has been described in a third of the cases and a palatal enanthem in almost as many. The latter consists of 5 to 20 pinhead-sized red spots, usually at the junction of the soft and hard palates, which appear in crops, darken in about 48 hr, and disappear after 3 or 4 days. Cutaneous lesions are unusual except for faint erythema or, rarely, a maculopapular eruption. Petechial hemorrhages and purpura are encountered sometimes, and other hemorrhagic manifestations, such as epistaxis, may occur.

Other manifestations are rare. These include abdominal pain of a type to suggest acute appendicitis, possibly due to swelling of mesenteric nodes, cardiac and pulmonary manifestations, such as tachycardia, cyanosis, signs of pericarditis, transient T wave changes, and enlargement of mediastinal lymph nodes or pulmonary parenchymal changes, and a variety of neurologic manifestations. The last include headache, blurring of vision, even convulsions, stupor, coma, bradycardia, stiff neck, the Guillain-Barré syndrome, and encephalitis.

Convalescence is sometimes slow and may be associated with marked prostration. Recrudescences are very common. Relapse has occurred in about 6 per cent of cases. Recovery is the rule, but death has been observed in a few instances from such complications as rupture of the spleen, respiratory paralysis in association with nervous system involvement, pneumonia, edema of the glottis, and hemorrhage from a deep tonsillar ulceration.

Blood Picture. The leukocyte count is usually increased but, in the first week especially, there may be leukopenia due to granulocytopenia. The leukocytosis is usually moderate (10,000 to 15,000 cells per cu mm), but it may sometimes be very marked. It is due to an increase in lymphocytes, and these, in the main, are of a peculiar type: their nucleus may be oval, kidney-shaped, or slightly lobulated, and the cytoplasm is often somewhat basophilic and may be vacuolated or foamy in appearance. The nuclear chromatin is usually coarse and irregular, and nucleoli are rarely seen. These cells make up 60 per cent or more of all the leukocytes.

The characteristic changes in the leukocytes may appear as early as the second day of illness or as late as the twelfth day. They attain a peak by the seventh to tenth day and persist usually for 1 to 2 months.

Anemia is extremely rare, but several instances of hemolytic anemia complicating infectious mononucleosis have been reported. Thrombocytopenia is rare, but in a few cases the clinical picture resembles that of idiopathic thrombocytopenic purpura. The bone marrow reveals a slight myeloid hyperplasia and immaturity; there may be an increase in lymphocytes.

The serum characteristically contains agglutinins against sheep red cells in high titer (heterophil antibodies, Paul-Bunnell test, see Chap. 110). This has been observed, in different series and according to the diagnostic criteria of the authors, in 60 to 100 per cent of cases. The Paul-Bunnell test is actually nonspecific. Anti-sheep agglutinins are present in titers up to 1:28 in most normal persons and occasionally even in a titer of 1:56. In various infections a titer of 1:112 and occasionally of 1:224 may be seen. Persons receiving injections of horse serum and horse immune serum may develop titers as high as any seen in infectious mononucleosis. For these reasons it is generally considered that, in the presence of clinical and hematologic findings suggestive of infectious mononucleosis, only a titer of 1:224 or higher can be interpreted as confirming the diagnosis. When there is doubt, a differential test is required. This is based on the observation that heterophil antibodies in normal serum, in horse serum sensitization, and in a variety of infections can be absorbed completely by guinea pig kidney. On the other hand, anti-sheep agglutinins in infectious mononucleosis are never completely removed by treating the serum with guinea pig kidney although they are, as a rule, completely removed by beef red cells. The differential test is carried out by absorbing a portion of the patient's serum with guinea pig kidney and another portion with beef red cells. After this the absorbed specimens are tested for sheep red-cell agglutination.

In infectious mononucleosis, highest heterophil antibody titers are found usually during the second and third weeks of illness and, as a rule, positive reactions last 4 to 8 weeks. The titer bears no relation to the severity of the disease or the degree of lymphocytosis. The serologic test for syphilis may become transiently positive.

Renal function is rarely impaired, but albumin and red cells may be found in the urine. The cerebrospinal fluid pressure may be moderately elevated, and pleocytosis due to lymphocytes may be found.

Diagnosis. Glandular enlargement, sore throat, fever, the characteristic cells in the blood, and an increased titer of heterophil antibodies are a combination of findings which makes recognition of infectious mononucleosis easy in most instances. However, as discussed earlier, some have been willing to define infectious mononucleosis quite broadly. It can be admitted that, in the absence of an identifiable specific etiologic agent, there is room for differences of opinion regarding the diagnostic criteria upon which one should insist. However, it seems reasonable to require a minimum of 20 per cent lymphocytes of the characteristic type at the time of the fever peak and a positive heterophil antibody reaction. In the absence of a positive heterophil antibody test, it is difficult to maintain this diagnosis. The paradox of a positive heterophil antibody test unaccompanied by characteristic clinical and hematologic features of infectious mononucleosis can be explained by persistence of the antibodies from an earlier unrecognized attack and, in rare instances, by a resurgence of heterophil antibodies with another illness.

The above criteria should help to differentiate infectious mononucleosis from other infectious disorders. It may be added that certain symptoms are so unusual in infectious mononucleosis that their presence militates against the diagnosis, namely, nasal discharge or congestion, paroxysmal harassing cough, sputum, chest pain, joint pains, painful or extremely tender lymph nodes, watery diarrhea, and hematuria or dysuria.

Lymphocytosis, relative or absolute, may be encountered regularly or occasionally in a number of the diseases with which infectious mononucleosis may be confused on clinical grounds. Marked leukocytosis (40,000 cells per cu mm or even higher), chiefly due to the presence of small lymphocytes of normal appearance, characterizes a benign disorder, *acute infectious lymphocytosis*, which has been observed chiefly in children and is accompanied by only mild constitutional manifestations and no lymphadenopathy, splenomegaly, or positive heterophil agglutination reactions.

The clinical picture may be like that of serum sickness, a condition in which lymphocytes quite

similar to those seen in infectious mononucleosis may be found and a positive heterophil antibody test may be obtained. The differential test is required to distinguish between the antibody reactions in infectious mononucleosis and the rise in titer produced by horse serum.

It is not rare for infectious mononucleosis to be confused with acute leukemia. Differentiation of the latter depends on the demonstration of very immature leukocytes ("blasts") in the blood or the bone marrow and the presence of anemia and thrombocytopenia, both of which are rare in infectious mononucleosis. The heterophil antibody test will be negative.

Treatment. There is no specific therapy. Sodium perborate mouth washes are recommended since Vincent's infection is frequently associated with infectious mononucleosis. From time to time many agents have been advocated, such as arsenicals, penicillin, the tetracyclines, chloroquine, and adrenocorticosteroid therapy, but such claims are difficult to evaluate. As a rule, without treatment, the irregular fever persists for 1 to 3 weeks, and subjective symptoms disappear in 2 to 4 weeks. Relapses are not uncommon and may be late, but recurrences are very rare. The positive heterophil antibody reaction may persist for as long as 5 or 6 months, rarely longer. In the rare instances of more than average severity, the corticosteroids may give symptomatic relief without harm resulting, provided that treatment is continued for only 5 to 10 days.

by recurrent episodes of fever, abdominal pain, chest pain, arthralgia, and rash, terminating in some instances in chronic renal failure secondary to amyloidosis. The illness has also been termed "benign paroxysmal peritonitis" and "periodic disease."

Epidemiology. Familial Mediterranean fever (FMF) occurs almost entirely in peoples originating in countries bordering on the coast of the Mediterranean—North Africa, Libya, Syria, Iraq, Iran, Armenia, Turkey, Spain, Italy, and Israel. Most patients have been Sephardic and Iraqi Jews (Jews who originated in this area, as opposed to Ashkenazi Jews most of whom stem from Eastern Europe) and Armenians. In the United States, the disease has been described in individuals of similar racial origin. The disease is frequent among siblings and rare among their antecedents. Consanguinity between parents of those affected is much higher than in the general population. These data indicate that the gene of FMF is inherited as a typical autosomal recessive trait. The ratio of affected males to females is approximately 3:2.

Etiology. The cause of FMF is not known. It is a genetically determined inborn error similar to Mediterranean anemia, sickle-cell disease, or congenital spherocytosis. No abnormal hemoglobins have been demonstrated. There is no evidence that FMF is an autoimmune or lipid storage disorder. Abnormal excretion of the amino acid, histidine, has been found in some patients. However, this has not been a consistent finding. Etiocholanolone (3 α -hydroxyetiocholan-17-one), a steroid hormone metabolite which has been found to be pyrogenic for man, may be implicated in the pathogenesis of FMF (see below).

Pathology. Biopsy of liver, spleen, bone marrow, lymph node, skin, and muscle have not revealed any lesions. Patients dying from renal failure have had amyloidosis involving the kidneys and other viscera.

Manifestations. Familial Mediterranean fever begins prior to the age of ten in 70 per cent of patients, and 95 per cent have their first attack before they are twenty years old. Episodes of fever, abdominal pain, chest pain, arthralgia, and erysipeloid rashes comprise the syndrome. An attack lasts 12 hr to 3 days; occasionally symptoms persist for 7 to 10 days. They recur at varying intervals; some patients are free of symptoms as long as a year, others have attacks once a week.

Fever. Fever is present in 100 per cent of patients and is the *sine qua non* for the diagnosis. The temperature ranges between 100.4 and 104°F, rises steeply, and usually falls abruptly. Pyrexia generally lasts 12 to 24 hr. In most instances the temperature is normal between attacks, but a few patients, particularly those with joint involvement, maintain low-grade pyrexia.

230 FAMILIAL MEDITERRANEAN FEVER

Robert G. Petersdorf and
 Ivan L. Bennett, Jr.

Definition. Familial Mediterranean fever is an inherited disorder of unknown etiology characterized

Abdominal Pain. Attacks of abdominal pain occur in 90 per cent of patients and are the presenting symptom in 40 per cent. The pain may be anywhere in the abdomen and may radiate to the shoulders, chest, or back. The abdominal wall may be doughy or rigid, with rebound tenderness, guarding, and absent bowel sounds—the hallmarks of acute peritonitis. It is not surprising, therefore, that many of these patients have been subjected to laparotomy. Vomiting frequently accompanies the attacks, but disturbances in lower bowel function are unusual.

Chest Pain. Some 80 per cent of patients have chest pain with or without concomitant abdominal pain. The pain is stabbing, knifelike, and pleuritic in character. It often radiates to the shoulder. Tachypnea is common, but dyspnea and cyanosis do not occur. Chest x-rays are normal except for occasional small accumulations of fluid in the costophrenic angles.

Arthralgia. Four-fifths of patients with FMF have involvement of the joints. Attacks of arthralgia vary widely in duration, intensity, and location. The ankle is most frequently involved, with other joints of the lower extremities next in importance. The joints are tender, and there is redness and swelling. As a rule, several joints are affected. Each episode lasts 1 to 3 days, and it is not unusual to observe mild fever between attacks. Most patients have no lasting functional impairment although, rarely, chronic deformities develop.

Cutaneous Manifestations. Almost 50 per cent of patients have some type of rash in association with the febrile attack. Usually this takes the form of well-demarcated, slightly raised, erythematous patches over the ankle joints, dorsums of the feet, and calves. As with the other components of FMF, the rash is evanescent.

Renal Involvement. About one-third of patients with FMF have proteinuria, and in about one-half of these excretion of protein in the urine exceeds 2.0 Gm per day. Several patients have developed the full-blown nephrotic syndrome—edema, hypoalbuminemia, and hypercholesterolemia—and at necropsy have shown classical amyloidosis.

The cardiovascular, central nervous, endocrine, and reticuloendothelial systems remain normal in FMF. Splenomegaly occurs in some patients, but since the majority also live in areas with a high prevalence of malaria and thalassemia, the significance of splenic enlargement is difficult to assess.

Laboratory Findings. Since the cause of FMF remains an enigma, it is not surprising that the patients have been subjected to extensive laboratory investigation. Aside from marked elevation in the sedimentation rate, leukocytosis with counts ranging between 10,000 and 20,000 cells per cu mm during attacks (but not during asymptomatic intervals), hyperfibrinogenemia, a questionable in-

crease in uroporphyrins, and sporadic increase in spherocytes in the blood, laboratory data are entirely normal. These include the hemogram, platelets, liver function tests, serum proteins and lipids, circulating hormone levels, and amino acid excretion patterns, except for histidine. Red cell fragility is normal, Coombs test is negative, and porphobilinogen absent. As has been mentioned, there are no significant microscopic lesions in any organ referable to FMF per se.

Diagnosis. The diagnosis of FMF is not difficult in the classical case occurring in an Armenian or a Jew with a positive family history and with recurrent attacks and relative well-being in the intervals between febrile episodes. The most difficult problem is presented by patients with signs of acute peritonitis, and many have had repeated exploratory operations. It is not uncommon for some of these patients who are familiar with their symptom complex to refuse surgical intervention. The differential diagnosis of fever should include malaria, relapsing fever, brucellosis, Hodgkin's disease and other lymphomas, and collagen-vascular diseases. However, the marked chronicity of FMF and lack of symptoms between bouts of pyrexia should distinguish FMF from other subacute and chronic febrile illnesses.

Articular involvement raises the question of rheumatoid disease, which can be ruled out by absence of positive sheep cell, latex, or bentonite flocculation tests and synovial biopsy.

The relationship of FMF to two other entities, "periodic disease" and "etiolocholesterol fever," is of interest.

Periodic Disease. In 1946 Reimann described a group of disorders characterized by short, regular episodes of a symptom complex which recurred over many years without affecting the patients' general health. He named these according to their outstanding clinical features such as periodic fever, periodic abdominalgia, periodic arthralgia, periodic neutropenia, periodic purpura, and periodic edema. The emphasis on the regular occurrence of these attacks is unfortunate because, in actuality, the majority of episodes in Reimann's patients occurred at irregular intervals, much like those in FMF. Furthermore, many patients described as having "periodic disease" clearly have had FMF. Others have had angioneurotic edema, Henoch-Schönlein (anaphylactoid) purpura, and a peculiar disorder, cyclic granulocytopenia, characterized by regularly recurring neutrophilic granulocytopenia, accompanied by anorexia, malaise, fever, and secondary infections such as stomatitis, pharyngitis, and pneumonitis. The last three disorders appear to be far removed clinically from the well-defined picture of FMF. The various periodic disorders were ascribed to some underlying occult rhythm, perhaps a neuro-

vascular disturbance. Since the cognomen "periodic disease" obviously represents several nosologic entities, there seems little to be gained by its use. "Benign paroxysmal peritonitis" merely refers to the abdominal aspects of FMF. Since it is not a benign process, the term is inaccurate and should be discarded.

Etiocholanolone Fever. In 1958 Bondy and his colleagues reported two patients with recurrent attacks of fever, abdominal pain, arthralgia, and leukocytosis whose main urinary steroid breakdown product during the febrile attack was etiocholanolone and who, at the same time, had unconjugated etiocholanolone in the plasma. This observation was of particular interest since it had previously been shown that a few specific steroids, notably etiocholanolone, were capable of producing fever when injected into man. It is postulated that these patients have one or several abnormal pathways for the metabolic breakdown of endogenous steroid products. This results in the intermittent appearance of etiocholanolone in the bloodstream followed by elevation in temperature. In contrast to etiocholanolone fever, patients with FMF have not been found to have abnormalities in steroid metabolism. Furthermore, the racial predisposition, amyloidosis, and histidinuria found in FMF are absent in etiocholanolone fever. Finally, some patients with this illness improve following administration of cortisone, which has been consistently ineffective in FMF. Despite these differences, some patients with etiocholanolone fever were of Jewish extraction, and one had a family history which was positive for similar febrile attacks. The relationship of etiocholanolone to FMF needs further clarification.

Treatment. A plethora of therapeutic regimens including antibiotics, arsenicals, and adrenal steroids has been tried in the treatment of FMF without avail. There is some indication that ACTH and cortisone enhance the deposition of amyloid and are contraindicated. A striking reduction in the number of attacks of FMF has been described following institution of a low-fat diet and exacerbations followed dietary indiscretions, particularly ingestion of foods high in fat. Whether fat per se or some other chemical moieties in fatty foods are responsible is not known at present.

Prognosis. Familial Mediterranean fever is a chronic disease, persisting throughout life. The only known ameliorating factor is pregnancy, and complete remissions are seen in gravid women. Since the disease appears predominantly in the young and middle-aged, it is conceivable that recovery takes place with advancing age. It is more likely, however, that the majority of patients die of renal failure and that the migratory habits of many patients with this disease have prevented adequate follow-up studies.

231 MIDLINE GRANULOMA

Lawrence E. Shulman

Definition. This peculiar condition, also known as *lethal midline granuloma* or *granuloma gangraenescens*, is characterized by progressive destruction of the soft tissues and bony structures of the face, terminating almost invariably in death after several months or a few years of illness. It occurs in young adults and the middle-aged and seems to be more common in men. The first case was described by McBride in 1897 and since then more than 100 cases have been reported, mostly in the otolaryngologic literature.

Etiology and Pathology. Not only is the etiology of midline granuloma unknown, but the category of disease in which it belongs is uncertain. There is disagreement as to whether it is primarily (1) infectious, (2) vascular or allergic, or (3) neoplastic. Only a few complete autopsy studies have been reported. In half of them, lesions have been found in skin, lungs, and mesenteric lymph nodes as well as the face.

Histologically, the lesions of midline granuloma vary from case to case and also from one area to another in the individual case. The most common

finding in the facial lesion is chronic inflammation. In the face and elsewhere there are focal areas of necrosis and necrotic small blood vessels, often containing granular thrombi, suggesting that the process is primarily vascular. The vascular lesions, however, differ from those of polyarteritis nodosa in that the characteristic inflammatory reaction of a true vasculitis is absent. Some areas contain large numbers of cells of varying sizes with large, pale, multilobulated nuclei, simulating Hodgkin's disease and mycosis fungoides. In other areas, hyperchromatic nuclei and numerous mitotic figures resemble those seen in undifferentiated tumors.

Clinical Features. Midline granuloma begins with a prodromal period of months to years of nasal obstruction and discharge, at first mucoid and later purulent. During this time, the patient is usually thought to have allergic rhinitis or sinusitis. Progressive inflammation and ulceration follow. The first ulcerations are found in the nasal septum, the mucosa or skin of the alae nasi, or the center of the palate. The lesions invade underlying cartilage and bone, giving rise to septal or palatal perforations. The condition spreads by local extension to involve the rest of the nose, paranasal sinuses, eyes, mouth, pharynx, and larynx. Eventually, the structures of the midface are totally destroyed by erosion. Gradually, the functions of sight, speech, and ventilation are impaired or lost. The end result is the formation of a large cavity, bounded above by the frontal bone and superior aspect of the orbits and below by the mandible, which is never affected.

During periods of activity, and especially preterminally, the patient becomes febrile. Usually the fever does not respond to appropriate chemotherapy for the secondary bacterial infection which is almost always present. Moreover, even in the presence of obvious pyogenic infection, the patient often fails to develop leukocytosis and during the later stages may become chronically leukopenic. Another curious feature is the absence of cervical lymphadenopathy during periods of active inflammation and progression of the disease. A few patients show red, raised, indurated areas on the skin of the legs and abdomen, resembling those of erythema nodosum clinically and histologically. There is no anemia, and the bone marrow and serum proteins are normal. Microbiologic investigations have failed consistently to detect a specific virus, bacterium, or fungus.

The course of the disease varies greatly; some cases last for more than a decade with long periods of quiescence and others are fulminant, ending fatally after a few months. Death usually results from meningitis, pneumonia, inanition, or massive hemorrhage.

Diagnosis. During the early phases of midline granuloma it is important to rule out several specific nasal and facial conditions, many of which are treatable. These include: leprosy, syphilis, yaws (gangosa), tuberculosis (lupus vulgaris), glanders, leishmaniasis, blastomycosis, and coccidioidomycosis, chromate poisoning; lupus erythematosus; also lymphomas, mycosis fungoides, and other malignant tumors. Midline granuloma is differentiated from Wegener's granulomatosis (p. 1000) by the absence of generalized polyarteritis nodosa and glomerulonephritis. Noma is readily distinguished by its being largely restricted to children, involving the cheeks and mouth, but not the nose.

Treatment. No effective therapy for midline granuloma has yet been found. The basic disease progresses despite administration of antibiotics or adrenocortical steroids. A few early reports of benefit following radiotherapy have not been substantiated by further experience, and nitrogen mustard have failed. Radical surgical excision is no more effective than conservative debridement. Various prostheses designed to maintain the integrity of the normal facial passages are helpful both functionally and cosmetically.

PART SEVEN

Reactions to Antigens and Other
Foreign Substances

Section 1 Reactions to Antigens and Other Foreign Substances 1257

Section 1: Reactions to Antigens and Other Foreign Substances

232 ALLERGY AND ITS MANIFESTATIONS IN MAN

Leighton E. Cluff

Definition. Allergy designates the adverse reactions, and immunity designates the protective reactions, observed upon exposure to a foreign substance (antigen) following an initial sensitizing or immunizing contact.

History. Acceleration of the local reaction to cowpox vaccination in immune persons was described by Jenner in 1801, and this was the first recognized immunologic reaction in man. Koch described the hypersensitivity reaction to tuberculin in individuals with tuberculosis in 1890. Severe systemic reactions, occasionally leading to death, following repeated intravenous inoculations of foreign protein into animals were described by Portier and Richet and by Theobald Smith in 1902. This phenomenon was called *anaphylaxis*, the antithesis of prophylaxis or protection. Rosenau and Anderson showed that anaphylaxis was elicited only by the specific antigen to which an animal had been sensitized. Von Pirquet coined the term allergy in 1907 to describe the altered reaction and clinical manifestations observed following exposure of human beings to foreign proteins.

Etiology and Pathogenesis. Allergy in man and in experimental animals may be of two types: (1) reactions associated with serum antibody, and (2) reactions unrelated to serum antibody. The allergic reaction unassociated with serum antibody is often referred to as *delayed hypersensitivity*, while the reaction related to serum antibody is referred to as *immediate hypersensitivity*.

Allergic reactions in man attributed to serum antibody primarily involve smooth muscle and blood vessels, as illustrated by hay fever, asthma, anaphylaxis, urticaria, and periarthritis nodosa, resulting in increased vascular permeability, edema, vasculitis, and probably smooth muscle contraction. Anaphylaxis, serum sickness, arteritis, and glomerulonephritis can be induced in experimental animals by injection of foreign protein or serum. These allergic reactions appear when antigen is in excess of serum antibody and soluble antigen-antibody complexes are present in the circulation, illustrating

the important quantitative relationship between antigen and antibody in the production of disease.

Delayed hypersensitivity reactions not related to serum antibody may not be primarily associated with vascular lesions, but are characterized by perivascular inflammation with mononuclear cells, and tissue injury possibly results from effects other than vasculitis and smooth muscle contraction. Allergic reactions to bacterial antigens following infection, such as the tuberculin reaction, contact dermatitis, and possibly others are attributed to delayed hypersensitivity.

The relationship of immediate hypersensitivity reactions to serum antibody is illustrated by passive transfer of the allergic state with serum. Delayed hypersensitivity reactions, on the other hand, can be transferred only with mononuclear cells from the allergic individual.

Most antigens of organic substances, including pollen, dust, and dander which are common causes of allergy in man, are proteins. Other substances capable of inducing an immunologic response, however, may be polysaccharides, chemicals such as drugs, and possibly lipids. From the classical studies of Landsteiner, Chase, and others, it is likely that chemicals or drugs, and frequently polysaccharides, become antigenic only when complexed to protein. In this way the chemical or polysaccharide serves as an antigenic determinant or *hapten*.

Although the character of an antigen may condition the type of immunologic response induced, the route of inoculation and the conjugated state of the haptens are of greater importance. For example, injection intradermally of a chemical such as picryl chloride into man or experimental animals results in the development of nonantibody-mediated or delayed hypersensitivity, whereas, injection of the same chemical intravenously results in development of antibody-mediated or immediate hypersensitivity.

Antibodies specifically associated with certain allergic diseases in man, such as hay fever, have features which distinguish them from antibodies of other types and frequently are referred to as *reagins*. Reagins are not detectable by the usual in vitro immunologic procedures (precipitation and complement fixation with antigen), they are less resistant to heat than other antibodies, and they are

firmly fixed in the skin at the site of inoculation. The presence of a reagin in serum correlates with the wheal and erythema elicited by intracutaneous injection of antigen, but bears no constant relationship to the presence or the severity of clinically significant allergic disease. Certain individuals have a particular propensity for developing reaginic antibodies, and as illustrated by immunization with diphtheria toxoid, individuals with a personal or family history of allergic disease, such as hay fever, urticaria, and asthma, develop "skin sensitizing" or reagin antibodies to diphtheria toxoid with greater frequency than persons without such a history.

There are important quantitative relationships between antigen and antibody that are required for the elicitation of a hypersensitivity reaction. For example, an Arthus skin reaction, characterized by acute inflammation and hemorrhagic necrosis, regularly can be induced only when the intracutaneous dose of antigen is specifically related to the amount of antibody an animal possesses. Furthermore, as mentioned previously, anaphylaxis and serum sickness are elicitable most readily only when antigen is in excess of the available specific antibody.

Serum complement often is involved in the interaction of antigen and serum antibody, and it is probable that complement plays an essential role in some allergic reactions. Allergic reactions associated with serum antibody are commonly characterized by the elaboration of histamine, proteolytic enzyme activity, and changes in blood potassium, adenosine, serotonin, heparin, "slow reacting substances," and other substances. None of these biochemical changes has led to a satisfactory understanding of the mechanisms of allergic disease in human beings, but the liberation of histamine probably accounts for the wheal and flare reaction of reaginic skin reactions and may account for some of the effects of hay fever, as these reactions can be reproduced with histamine and are alleviated with histamine inhibitors.

The ability to produce reagin, as indicated above, is probably genetically determined, although this has not been satisfactorily defined. In addition, selective animal breeding can result in evolution of strains with varying immunologic responsiveness. Congenital agammaglobulinemia characterized by a defect in serum antibody synthesis is a gross example of varying immunologic responsiveness in the human being. There are, in addition, acquired diseases that may significantly alter immunologic responsiveness, illustrated by the failure to develop delayed hypersensitivity in sarcoidosis and Hodgkin's disease. Furthermore, patients with lymphatic leukemia are often defective in the ability to produce serum antibody, as also are patients with multiple myeloma. Experimentally, it has been

shown that exposure to ionizing radiation can impair immunologic responsiveness.

Allergy, itself, is not inherited, but the existence of a *familial predisposition* to its development seems firmly established, and familial allergic disease is commonly called *atopic*. About 50 per cent of patients with hay fever or asthma will have a family history of allergic disease, as opposed to only 15 per cent of the remaining population.

The characteristics of antigen, antibodies, and the immunologic mechanisms probably associated with certain allergic diseases of man are listed in Table 232-1.

Hyposensitization or *desensitization* has been the principal means of specific treatment in allergic disease of man. The immunologic mechanisms involved in specific reduction of hypersensitivity reactions have been extensively studied but still are poorly understood. In experimental animals and in the human being, desensitization can be accomplished by two principal methods of antigen administration: (1) by repeated and frequent injection of small but increasing doses of antigen over an extended period of time, and (2) by injection of a large dose of antigen in one inoculation or several doses over a short period of time. The first method is the one commonly used in desensitization of patients with allergic diseases such as hay fever and asthma, while the second is usually employed in desensitization of patients to horse serum.

Injection of a large but sublethal dose of antigen into the sensitive individual is followed by decrease or disappearance of specific serum antibody, and the accompanying desensitization persists as long as the serum antibody is suppressed. When the serum antibody reappears, however, sensitivity to the antigen reappears.

Repeated and frequent injection of antigen into the sensitive individual may not result in a decrease but may result in a rise in serum antibody levels. It has been suggested that one possible explanation for desensitization accomplished in this way is a change in the quantitative relationships between level of antibody and dose of antigen required to elicit a hypersensitive reaction. In other words, as the antibody titer rises, larger amounts of antigen would be required to elicit a hypersensitivity reaction, and there is decreasing reactivity to doses of antigen that were previously harmful.

From the studies of Cooke and Loveless it seems clear that in atopic or reaginic disease there may be an alternative explanation for desensitization in man accomplished by repeated injections of small doses of antigen. Following *parenteral* injections of pollen antigens into the sensitive or normal person, an antibody (*blocking antibody*) may develop that can block the reaction of antigen with reagin. The

±—inconclusive evidence; ?—unknown.

"blocking" antibody is heat stable and does not become fixed in the skin at the site of injection, distinguishing it from reagin. Reduction in sensitivity by repeated injection of small doses of antigen, whether attributable to increased levels of serum antibody or appearance of blocking antibody, may persist for a very limited period of time.

Nonspecific desensitization or suppression of allergic reactions can be accomplished with a variety of drugs and other substances. For example, adrenal cortical steroids can suppress the inflammation associated with cellular hypersensitivity but are less effective in suppressing most reactions in experimental animals mediated by serum antibody. In this respect, it is of interest that adrenal steroids

have such a profound effect in suppressing the symptoms of hay fever, urticaria, and serum sickness which are probably mediated by serum antibody. Antihistamines, bacterial endotoxin, and many other substances also will reduce many experimental and clinical allergic reactions.

HAY FEVER

Definition. *Hay fever* is characterized by sneezing, rhinorrhea, itching of the eyes, and lacrimation. It is most commonly attributed to pollen antigens in the air and, therefore, occurs during particular seasons of the year. *Allergic rhinitis* is not necessarily seasonal and can develop upon exposure to airborne

antigens other than pollen. *Vasomotor rhinitis* designates perennial allergic rhinitis as well as other nasal diseases that may not be allergic but are characterized by symptoms resembling hay fever.

Etiology. The immunologic mechanisms associated with hay fever, characterized by the presence of serum reagin, familial history of allergic disease, and wheal and erythema reactions in the skin following injection of specific antigen, have been described. Of particular importance and interest in hay fever are the pollens which serve to induce the immunologic response and elicit the hypersensitivity reaction responsible for producing rhinitis. Plants which depend on the wind for cross-pollination are common sources of antigens responsible for hay fever. Plants that are pollinated by insects, including most flowering plants such as roses and golden-rood, are not important causes of hay fever.

Ragweed pollen is the principal offender responsible for hay fever in the United States. It is prevalent in the central, eastern, and southeastern part of the country, virtually absent in the northwest, and west of the Rocky Mountain states, and of little importance in the southwest. Ordinarily, ragweed pollinates between the first of August and the end of October, and early fall is the most likely season for a patient to experience symptoms of ragweed hay fever.

Grass, weed, and tree pollens also are important causes of hay fever in this country. In the northern half of the country, grasses pollinate from May to July, while in the south, grass may pollinate throughout the year.

Although the time of year when trees pollinate may vary, they ordinarily do so in early spring, and earlier in the south than in the north.

Most pollen particles are about 25 to 40 μ in diameter and, therefore, settle promptly from the air, varying, of course, with wind velocity. The settling properties of airborne pollen are used for crude estimations of the "pollen count" in the air by collecting and enumerating particles on a greased glass slide. There is an approximate but regular correlation between the pollen count and the frequency of occurrence and severity of hay fever in the exposed population.

The relatively large size of pollen particles is of importance in considering the pathogenesis of hay fever. Most particles the size of pollen suspended in the air will be impinged and deposited within the nose during inhalation. Very few if any of the particles would be expected to reach the terminal bronchioles.

Wind velocity, humidity, temperature, time of day, and other meteorologic conditions undoubtedly influence the aerodynamics of pollen and are of importance in explaining the variations in severity of hay fever with changing climatic conditions. For

example, rain causes a sharp decrease in the concentration of large particles, including pollen, in the air, although it may not affect the concentration of airborne particles less than 5 μ in size.

Pollen particles from plants, grasses, or trees of varying types can be differentiated by microscopic examination, enabling one to define precisely the airborne pollens likely to be responsible for hay fever.

Other airborne antigenic particles have been incriminated in the etiology of perennial allergic rhinitis, including material from feathers, dust, animal danders, facial powders, fungus or molds, clothing, and food particles disseminated during cooking.

The specific antigenic determinants in pollen, dust, and other airborne particles responsible for allergic rhinitis have not been precisely characterized.

There is evidence suggesting that the nasal mucosa of the patient with hay fever or allergic rhinitis is more susceptible to the inflammatory effects of inhaled irritants than is the nasal mucosa of normal persons. Furthermore, recent studies in volunteers indicate that persons with allergic rhinitis are more susceptible to infection by respiratory viruses than are normal persons. This enhanced reactivity of the nasal mucosa to a variety of stimuli also may explain the effects of emotional disturbances in exaggerating and possibly initiating symptoms of rhinitis in the allergic individual.

Manifestations. Pruritus about the eyes, nose, throat, and mouth, nasal discharge, sneezing, and lacrimation are the characteristic features of hay fever or allergic rhinitis. Particularly troublesome to the patient is occlusion of the nasal airway, making breathing difficult and often causing insomnia. Symptoms vary in severity from day to day and from one patient to another. This variability in the symptoms of hay fever can be explained partly by changing concentration of airborne antigens, but the variability between patients is not always easily understood.

The nasal mucosa usually is pale and edematous, but may appear hyperemic if the disease persists. The conjunctiva and the skin about the eyes, nose, and occasionally the mouth often are reddened. Microscopic examination of the nasal secretions may show many eosinophils.

Occlusion of the nasal passages by swelling of the turbinates and mucous membranes may result in obstruction of the sinus ostia or the Eustachian tube, and infection of the sinuses and middle ear is a relatively common complication of perennial allergic rhinitis but uncommon in seasonal hay fever. In addition, infection of the sinuses or nose in patients with allergic rhinitis results in formation of *polyps* of the nasal mucosa. These polyps can fur-

ther obstruct the nasal passages and cause more severe symptoms and exaggerate infection. It is unusual to observe nasal polyps in the absence of nasal or paranasal infection. When sinusitis develops in the patient with allergic rhinitis, polyps may form also in the sinuses; these are recognizable radiologically.

Many persons with hay fever or allergic rhinitis subsequently may develop asthma. Retrobulbar neuritis, laryngeal edema with hoarseness, angioedema, urticaria, and other allergic illnesses occasionally accompany allergic rhinitis.

Diagnosis. Symptoms resembling those of allergic rhinitis or hay fever can occur in other situations where allergy cannot be incriminated. It is a common experience, for example, to develop sneezing, watery nasal discharge, and lacrimation upon exposure to an atmosphere heavily contaminated with smoke, dust, or other irritants. Similarly, these same symptoms often herald the onset of a viral upper respiratory tract infection. It is important to remember that the symptoms of hay fever are attributable to nonsuppurative inflammation of the nasal mucosa, and any situation resulting in inflammation of the nose can produce an illness often indistinguishable from allergic rhinitis. In addition, the nasal mucosa of the patient with allergic rhinitis is much more susceptible to the inflammatory effects of irritants, and exposure to irritants can result in nasal symptoms that ordinarily would not occur in normal persons. Ingestion of alcoholic beverages and emotional stimuli may also produce hyperemia of the nasal mucous membranes, exaggerating the symptoms of allergic rhinitis. *Polycythemia vera* may occasionally be recognized initially because of nasal and conjunctival hyperemia, resulting in symptoms resembling hay fever.

The pale and edematous appearance of the nasal mucosa often is helpful in distinguishing allergic rhinitis or hay fever from other conditions. In addition, the presence of nasal polyps is characteristic of allergic nasal disease, although indicative of coexistent infection in the nose or sinuses.

Of great importance in the diagnosis of hay fever is its seasonal occurrence, coinciding with pollination of weeds, grasses, or trees. The nonseasonal character of perennial allergic rhinitis makes it less readily recognizable. Examination of nasal secretions for eosinophils, however, is often helpful. Blood eosinophilia is also occasionally found in patients with allergic rhinitis.

Skin Tests. Approximately 25 per cent of the normal population will have wheal and erythema skin reactions when tests are made by the intracutaneous inoculation of common airborne antigens. Not all these persons with positive skin test reactions, however, have allergic rhinitis or hay fever. Nevertheless, individuals with serum reagin de-

monstrable by skin testing are more likely to develop allergic respiratory disease than are persons without such positive reactions. Commonly, it is found that the allergic patient will have positive skin reactions to many antigens even though it may not be possible specifically to incriminate any one of them as responsible for the production of symptoms of allergic disease. Therefore, skin tests with antigens potentially capable of causing allergic rhinitis or hay fever are of greatest value in detecting the presence of an allergic propensity rather than detection of the specific antigen responsible for the patient's symptoms. Only by careful correlation of the skin test reactivity with the environmental circumstances when the patient develops symptoms of rhinitis is it possible to delineate the incriminated antigen. Therefore, antigens for skin testing should be selected from those probably responsible as determined by a careful historical analysis of the situations when the patient experiences his symptoms.

Skin tests usually are performed with crude aqueous extracts of dried pollen, dust, foods, animal fur, insects, and other substances considered potentially capable of causing allergies. These antigen extracts are commercially available. The potency of the extracts may vary considerably, and a number of criteria have been devised for standardization. None of these methods of standardization, however, is very reliable, as the extracts are crude and the measurement of specific antigen in the extracts at present is impossible. The techniques for standardization are: (1) the pollen unit of Noon, representing the extract from 1 μ g of pollen; (2) weight by volume and dilution method, representing dilutions of a concentrated extract, (3) protein nitrogen unit, 1 unit representing 0.01 μ g of chemically determined protein nitrogen in the extract. None of these systems is satisfactory but may facilitate standardization of extract potency in use in a single clinic or from a single source.

Skin tests are done by application of a drop of antigen to a skin scratch or by intradermal inoculation of 0.01 to 0.02 ml to produce a small welt in the skin. In the beginning, very dilute extract should be used for skin testing as large amounts of antigen may produce severe systemic reactions in the allergic patient. The concentration of antigen may be gradually increased until one is satisfied that the patient has a negative reaction. Ordinarily, it is unwise repeatedly to test a patient on the same day or to test with a large number of extracts at one time. Positive reactions to extracts of antigens responsible for hay fever or allergic rhinitis usually are apparent within 15 to 20 min and are characterized by wheal and erythema and by local pruritis. When large doses of extract are given, symptoms of hay fever or even a generalized

reaction may be produced. Occasionally, reactions may be delayed and result in erythema and induration at the site of injection at 24 hr. The importance of such reactions in diagnosis of allergic respiratory disease is not clear. The scratch skin test ordinarily is safer than the intradermal injection of antigen, although the latter is more reliable and reproducible.

Extracts of foods are available for skin testing, but their use should be limited as it is preferable to diagnose allergy to foods by anamnesis and by elimination diets.

Extracts of bacteria and killed bacterial vaccines for skin testing are useful, of course, in the diagnosis of certain types of infection, but the relationship of hypersensitivity to respiratory microorganisms in the production of allergic rhinitis is far from clear. Until this relationship is better defined, it is impossible to place any diagnostic significance upon positive reactions in the diagnosis of allergic respiratory disease. Cultural identification of bacteria in the respiratory tract potentially responsible for infection is of greater use than skin testing.

When it is undesirable to perform skin tests in a patient, such as in young children or persons with generalized skin disease, passive transfer of the patient's serum to normal recipients may be performed (Prausnitz-Kustner or P-K). Ordinarily, 0.05 to 0.1 ml of the patient's serum is injected intradermally into the recipient, and 24 hr later normal skin and sites injected with serum are tested with the antigenic extracts.

Epinephrine and ephedrine greatly reduce the wheal and erythema response to intradermally injected antigen, as do large doses of antihistamines. These drugs should not be administered to the patient, therefore, prior to skin testing. Adrenal cortical steroids have little effect upon these reactions.

Although diagnostic testing with antigen extracts of patients with allergic disease is useful in determining the degree of skin hypersensitivity and the variety of antigens to which the patient may have demonstrable serum reagin, this technique is not adequate by itself for identifying the agent responsible for allergic symptoms. Skin testing is only one aspect of the diagnostic methodology and must be weighed in relationship to information derived from history, physical examination, and a careful definition of the environmental circumstances associated with development of symptoms of illness.

Therapy. Specific Treatment. Elimination of the offending antigen from the patient's environment is the most effective means of controlling allergic disease. This is not always easy, even when the antigen is known. If it is determined that dander from dogs or cats is responsible, for example, then animals should be avoided. When feathers are found to be responsible for allergic symptoms, a feather

pillow should be replaced by one of foam rubber. Air filtration is often useful in controlling symptoms due to airborne pollens, but occasionally it may be necessary to advise the patient to live in a pollen-free area during the season of the year when he experiences hay fever. Mechanical obstruction of the nasal airway, which may aggravate the symptoms of rhinitis, should be corrected. Infection, if present, should be treated with an antibacterial drug capable of eradicating the specific microorganism. Alleviation of emotional disturbances by the use of drugs, correction of the environment, or psychiatric guidance occasionally will assist materially in alleviating the symptoms of allergy.

Desensitization, hyposensitization, or immunization with the antigens recognized as specifically responsible for allergic respiratory disease is effective. Controlled studies of desensitization in patients with hay fever due to ragweed pollen have shown that approximately 80 per cent of patients are relieved of their symptoms, whereas about 25 per cent of patients given placebo are improved. The possible mechanisms involved in alleviation of the manifestations of allergy accompanying the injection of antigen for desensitization were discussed before.

Treatment by desensitization may be perennial, coseasonal, or preseasonal. Continued therapy throughout the year probably is preferable to discontinuous treatment, but the dose of antigen in some patients must be reduced considerably during the season of the year when the patient's symptoms are expected to occur.

In some instances, the beneficial effects of desensitization may persist after the inoculations are discontinued, but more often, the allergic symptoms recur. Recently, the beneficial effects of desensitization have been obtained by injection of antigens in adjuvant containing mineral oil and an emulsifier. One injection given prior to the season when symptoms will appear has produced results equivalent to desensitization by repeated injection of the aqueous extract. Ordinarily, 100 to 3,000 protein nitrogen units of ragweed pollen extract is incorporated into the adjuvant for desensitization. Some individuals given such injections have developed sterile cysts at the site of inoculation. Although this method of desensitization holds great promise, it cannot yet be generally recommended.

Bacterial vaccines have been employed in desensitization of patients with allergic rhinitis. The lack of evidence for bacterial hypersensitivity as a cause of allergic respiratory disease and the lack of conclusive evidence for the effectiveness of such treatment in allergic rhinitis indicate that it cannot be generally recommended.

Nonspecific Treatment. If treatment of hay fever is begun when symptoms are present, only meas-

ures to relieve manifestations of the disease should be employed. Furthermore, many patients can be relieved of their complaints with symptomatic remedies alone. The severity, recurrence, and refractoriness to symptomatic treatment of the illness will determine whether or not specific desensitization should be attempted. Antihistamines such as Pyribenzamine (50 mg), Benadryl (50 mg), Chlortrimeton (4 mg), and many others often are effective in controlling hay fever. Repeated use, however, frequently is associated with a gradually decreasing effectiveness of the drugs, but when one fails another may be effective. In addition, they may produce drowsiness and reduce physical and mental dexterity in 10 per cent of patients depending, of course, on dosage. Although very useful therapeutic agents, therefore, they have certain features limiting their application.

Adrenal cortical steroids given orally are extraordinarily effective in relieving the symptoms of most patients with allergic respiratory disease and were it not for their side effects could be generally recommended as drugs of choice in hay fever. Nevertheless, they can be used in the management of acute symptoms, and in some patients very small doses will completely suppress the symptoms during an entire season when administered daily. Hydrocortisone in dosage of 25 to 100 mg each day is usually quite effective. In addition, prednisone in a dosage of 5 to 20 mg and methylprednisone in a dosage of 4 to 12 mg will serve equally as well as hydrocortisone in the treatment of hay fever. This form of therapy cannot be generally recommended. Adrenal steroids can cause a remarkable disappearance of nasal polyps when used in patients with rhinitis and hay fever.

A variety of agents are available for shrinking the nasal mucous membrane to relieve obstruction of the nasal airway in rhinitis. Aqueous Neosynephrine ($\frac{1}{4}$ or $\frac{1}{2}$ per cent) is an effective nasal decongestant that can be useful in patients very uncomfortable from hay fever or allergic rhinitis until other remedies can correct the underlying disease. Repeated use of the drug, however, can cause reactive hyperemia of the nasal mucosa, further exaggerating the symptoms of rhinitis. Orally administered ephedrine (15 mg) or Propadrine hydrochloride may also be used to shrink nasal mucous membranes, but they have limited effectiveness.

ASTHMA

Definition. Asthma is characterized by expiratory dyspnea, cough, overinflation of the lungs, expiratory wheezing, and rhonchi. It is attributed to partial bronchial airway obstruction and often is caused by allergy to inhaled antigens. The symptoms fre-

quently are episodic and may develop during particular seasons of the year. Respiratory infection and other conditions occasionally associated with partial bronchial airway obstruction may produce symptoms indistinguishable from allergic asthma.

Etiology. Asthma commonly is attributable to: (1) allergy to inhaled antigens, when symptoms may be seasonal or perennial; (2) respiratory infection, when symptoms may be intermittent or chronic; and (3) a combination of infection and allergy to inhaled antigens, when symptoms may be seasonal, intermittent, and chronic.

Airborne antigens such as plant pollen, animal dander, dust, molds, or fungi and other substances may be the cause of asthmatic symptoms as well as hay fever and allergic rhinitis. In addition, the immunologic relationships probably are alike in hay fever and allergic asthma.

Bronchial airway obstruction associated with asthma invariably is generalized and may be produced by accumulation of secretions in the bronchial lumina, edema of the bronchial mucosa, hypertrophy of the bronchial wall, contraction of bronchial smooth muscle, dilatation of the bronchial and pulmonary blood vessels, or a combination of these. In allergic asthma, it is probable that mucosal edema, bronchial secretions, and bronchospasm are the principal mechanisms producing airway obstruction. It is likely that the small bronchioles initiate the reaction, although the entire respiratory mucosa may be involved.

The bronchial lumina increase in diameter upon inspiration and become narrower upon expiration, resulting in airway obstruction most pronounced during exhalation and producing high-pitched wheezing or whistling sounds in the chest. Expiratory dyspnea requires the use of accessory muscles to deflate the lung, increasing the intrathoracic pressure. During inspiration, the negative intrathoracic pressure often is noticeable by retraction of the intercostal, suprasternal, and supraclavicular spaces. The expiratory airway obstruction in asthma leads to hyperinflation or emphysema of the lungs. The emphysema accompanying episodic allergic asthma, however, is reversible (see p. 1514).

The precise mechanism producing dyspnea in asthma is not known, but this symptom probably results from several events, including a conscious recognition of obstruction to breathing, hyperinflation of the lungs, changes in intrapleural pressure, and the increased work involved in respiration. A consequence of the airway obstruction is an increase in residual air in the lung, with a corresponding decrease in breathing reserve. To maintain air exchange additional effort is required, leading to fatigue, which can further exaggerate dysp-

Orthopnea is a common feature of asthma but

undoubtedly is attributable to an entirely different mechanism than the orthopnea of cardiac failure. Elevation of the diaphragm while in the horizontal position reduces the respiratory reserve, making the asthmatic patient more dyspneic. The sitting posture, leaning forward to reduce the intraabdominal pressure and to allow the viscera to move downward and forward, probably improves the breathing reserve and the dyspnea.

During the early and less severe stages of asthma there may be *hyperpnea*, in excess of that required for gas exchange, and the blood CO_2 may fall below normal. When the disease is severe, and particularly when protracted, however, there often is oxygen unsaturation and increased CO_2 in the blood. Frequently, in this stage, and possibly attributable to fatigue, the patient's respiratory rate may be slowed, exaggerating the impaired ventilation caused by airway obstruction.

Anoxemia in asthma may lead to an increase in pulmonary vascular resistance and pulmonary blood pressure. Little is known, however, of the vascular abnormalities that accompany asthma, although the development of right ventricular hypertrophy and heart failure may be late complications of the disease.

The physical properties of the *bronchial secretions* undoubtedly influence the manifestations of asthma, but very little is known of the changes that may occur in sputum viscosity, elasticity, and stickiness. The ease with which sputum can be evacuated from the bronchi, however, obviously is an important factor in the severity of airway obstruction.

It has long been suspected that the *autonomic nervous system* is incriminated in the pathogenesis of asthma. The administration of acetylcholine, mecholyl, or cholinesterase inhibitors will induce symptoms of partial airway obstruction which can be alleviated by atropine. There is no clear evidence, however, indicating the importance of parasympathetic activity, and atropine usually is of no value and may have a deleterious effect in allergic asthma. Drying of bronchial secretions following administration of atropine may decrease the fluidity of bronchial mucus, however, and be responsible for its ineffectiveness.

Similarly, *histamine* has been incriminated in the pathogenesis of asthma, as administration of this drug can produce bronchoconstriction and expiratory dyspnea in man and experimental animals. This effect of histamine, however, can be nullified with antihistaminic drugs, whereas, these drugs have little effect upon asthma. In addition, *serotonin* has been shown to produce asthma-like symptoms, but its relation to allergic asthma has not been shown conclusively.

Parasympathomimetic drugs, histamine, and sero-

tonin will induce expiratory dyspnea in patients with a propensity to asthma, in doses ordinarily incapable of inducing such a reaction in normal persons. This increased reactivity in asthmatic patients is not confined to their response to drugs as they also may have an increase in bronchial airway resistance during respiratory infection and upon the inhalation of irritants, but this peculiar responsiveness is unexplained.

Besides the increased reactivity of the bronchial tree to drugs, inhaled irritants, and infection, it is clear that *emotional disturbances* may exaggerate or precipitate asthma. The mechanisms involved are not known, but may resemble those in animals in which it has been possible to produce manifestations of anaphylaxis by stimuli, such as bell ringing, inducing a conditioned response.

Manifestations. Expiratory wheezing, dyspnea, and cough, occurring spasmodically, are the characteristic features of asthma. These symptoms are worse during effort, are exaggerated by anxiety which almost invariably accompanies each attack, and may be most severe at night. During a paroxysm there is orthopnea, and the patient is most comfortable in a sitting position with the trunk bent forward and the arms elevated to rest at shoulder level. Dyspnea is most pronounced, and wheezing and rhonchi are audible, during expiration. There is prolongation of the expiratory phase of respiration, and inspiration characteristically is not so difficult as expiration. The wheezing and rhonchi are heard *throughout the chest* in asthma, and *localized wheezing* is indicative of some other cause of bronchial obstruction (see p. 1552).

Cough frequently becomes more severe during recovery from an asthmatic attack, when sputum seems more liquid and is produced in larger quantities. Occasionally, cough is so severe as to make the patient vomit. The sputum produced during paroxysm usually is white and mucoid, containing no blood or pus. Occasionally, however, if cough is severe or if the attack is protracted (*status asthmaticus*), the sputum may contain traces of blood. Microscopic examination of the sputum may show large numbers of eosinophils and occasionally crystals (Curschmann's spirals). In addition, as an asthmatic attack subsides, mucus casts of the bronchi or bronchioles may be seen in the sputum (Laennec's perles). Purulent sputum is indicative of bronchial or pulmonary infection as a cause of the asthma or as a complication of allergic asthma.

Hay fever and urticaria sometimes precede development of asthma, or occur simultaneously, and suggest that the asthma is attributed to inhaled or ingested antigen and reaginic or atopic allergy. This type of asthma is observed most commonly in young persons and usually is seasonal (*extrinsic asthma*). Nonseasonal asthma may also be attributed to al-

lergy to inhaled antigens such as dust, feathers, animal dander and to ingested foods or drugs. Older persons, however, most often have nonseasonal asthma which characteristically is associated with respiratory infection such as sinusitis, bronchitis, or pneumonia (*intrinsic asthma*), but may have symptoms more commonly in winter. Airborne or ingested antigens are not always associated with chronic asthma in adults, but may complicate the symptoms attributed to recurrent infection. Inhaled molds and fungus spores have been related to asthma in young and old individuals, particularly when the person is exposed to a damp or wet environment.

During severe attacks, hypoxia may lead to cyanosis, but rarely does this result in coma and death. Status asthmaticus, however, usually is accompanied by fatigue and exhaustion. In addition, if the patient does not drink, dehydration may develop, and failure to eat can further exaggerate the fatigue and exhaustion. Dehydration is associated with drying of the bronchial mucus, and this can make the patient's asthmatic symptoms more severe.

There is no fever unless asthma is caused by or associated with infection. After a prolonged attack the patient may complain of soreness in the chest or abdomen as well as tiredness, but otherwise there usually are no systemic manifestations of the disease. Examination of blood often shows eosinophilia but no leukocytosis, and the urine is normal.

Spontaneous pneumothorax and mediastinal emphysema rarely are complications of an asthmatic attack. Ordinarily, asthma does not affect cardiac function unless protracted or accompanied by irreversible emphysema, when cor pulmonale may develop. Usually, episodic asthma is benign and does not result in death. Patients may be crippled by their disease, however, because of intractable or frequently occurring paroxysms. With these qualifications, the prognosis is good.

Diagnosis. A history of allergic disease in the family, seasonal attacks of nasal or bronchial symptoms, and manifestations such as urticaria or hay fever are helpful in recognition of allergic asthma. Furthermore, asthma occurring during particular seasons or under certain environmental circumstances facilitates detection of the offending antigen.

As previously mentioned, localized wheezing in the lungs is not a manifestation of asthma but is indicative of endobronchial disease, such as foreign body aspiration, neoplasm, or stenosis. In contrast to these conditions, the lungs are usually normal between paroxysms of uncomplicated asthma. Generalized wheezing predominantly occurs during expiration, whereas in bronchiectasis, acute pulmonary edema, or pneumonia there are inspiratory rales as well. Of course, asthma complicated by

pneumonia may be associated with signs of parenchymal lung disease. The presence of inspiratory moist rales, bloody sputum, and cardiomegaly in acute pulmonary edema or "cardiac asthma" usually enables its differentiation from paroxysmal asthma.

Asthma occasionally is a presenting manifestation of polyarteritis nodosa (p. 1889). Drug reaction, particularly with aspirin, is an occasional cause of severe asthma in patients with respiratory allergy attributed to other causes. Loeffler's allergic pneumonitis, occasionally due to parasitic infestation of the lungs, is often accompanied by asthma (p. 1556).

Poisoning with cholinergic drugs or insecticides may induce bronchoconstriction and expiratory dyspnea which can be specifically relieved with atropine. Carcinoid tumors elaborating serotonin may be associated with asthma. In addition, traumatic cerebral disease may result in asthmatic symptoms. There are examples of outbreaks of asthma in a large population or in individuals exposed to irritants in polluted air. Furthermore, silo-filler's disease and farmer's lung disease may be associated with asthma attributed to inhalation of nitrogen dioxide or microorganisms which cause inflammation in the bronchial tree (pp. 1532 and 1533).

Skin tests used for the diagnosis of asthma are no different from those used for the diagnosis of hay fever and were described previously. There are no specific laboratory tests that will define the allergic etiology, but measurements of pulmonary function will demonstrate the presence of increased airway resistance. The finding of increased numbers of eosinophils in sputum and blood, however, occasionally will suggest an allergic cause of asthma.

Therapy. Specific Treatment. Elimination of the offending antigen from the patient's environment is the most successful means of preventing and treating allergic asthma, as in hay fever. Similarly, mechanical obstruction of the tracheobronchial tree should be corrected, and infection of the sinuses should be treated.

Specific desensitization or hyposensitization of the patient with asthma due to inhaled antigens can be done as in hay fever but may be less effective, and improvement usually does not persist when desensitization is discontinued.

The frequent occurrence of bronchial infection in adults with nonseasonal or chronic asthma necessitates special consideration. The pneumococcus and *Hemophilus influenzae* are the microorganisms most often isolated from the bronchi and sputum of patients with asthmatic or chronic bronchitis, and exacerbations of symptoms with cough and dyspnea may be associated with an increase in

number of these bacteria. Treatment of these patients with tetracycline (0.5 to 1.0 Gm per day) continuously, during winter months or upon the appearance of increasing symptoms, will decrease significantly the severity and frequency of exacerbations of their symptoms. Such treatment frequently is associated with a decrease in number of pneumococci and hemophili in sputum. Untoward consequences of this treatment in these patients are rare.

Chronic asthma with or without bronchitis may be complicated by acute infection by pneumococci, *Klebsiella pneumoniae*, or staphylococci, and when these infections appear they should be treated specifically with an appropriate antibiotic.

Nonspecific Treatment. Treatment of acute asthma is most effective when begun soon after onset of the paroxysm. Prompt relief can usually be achieved by subcutaneous injection of epinephrine, 0.2 to 1.0 ml of a 1:1,000 solution, repeated as needed, but no oftener than every 30 min. It is advisable to administer a sedative, such as phenobarbital, 60 to 90 mg, with epinephrine to allay agitation and to relieve the anxiety accompanying an attack of asthma. Epinephrine may become ineffective after repeated use. It may be used in oil, 1.0 ml of a 1:100 solution and injected intramuscularly for prolonged effect, and may be vaporized as a 1:100 aqueous solution for inhalation. Nebulized epinephrine analogues can be administered by the patient, but, if used repeatedly, irritate the respiratory mucosa. Aminophylline is an active bronchodilator which is beneficial in the person refractory to the action of epinephrine. It may be used occasionally in preference to, or in addition to, epinephrine, and may be given intravenously, rectally, or orally in decreasing order of effectiveness. The dosage is 0.25 to 0.5 Gm. When given intravenously, the drug must be given slowly. Rectal administration as a suppository or in water or oil is effective. If the patient is cyanotic, oxygen may be given but should be used intermittently, particularly if chronic diffuse lung disease is present. Ether administered rectally or as a general anesthetic occasionally may be successful in halting a severe attack of asthma. Adrenal cortical steroids may be given in severe or intractable paroxysms in the same dosage as described for hay fever, but are not always effective. Continuous administration of adrenal cortical steroids to the patient with chronic asthma or asthmatic bronchitis has been shown to be an effective and safe means of preventing patients from becoming crippled by this disease. This treatment has been continued for several years without serious side effects or complications. In fact, patients with severe asthma and infection have fewer episodes of infection while re-

ceiving adrenal steroids continuously. Steroid dosage may be increased if exacerbations occur while the patient is receiving the drug continuously.

If an asthmatic episode is unresponsive to the use of epinephrine and aminophylline, or recurs promptly, it may be advisable to give an intravenous infusion of 1 liter of 5 per cent glucose containing 0.25 to 0.5 Gm aminophylline. Morphine should never be given to the patient with acute asthma, but Demerol, 50 to 100 mg, is useful as a sedative and antispasmodic. Hydration should be maintained to prevent inspissation of bronchial mucus.

Prophylactic management of the asthmatic patient involves the use of drugs with which the patient can abort paroxysms and institution of measures directed to improve general health. Oral ephedrine (25 to 50 mg) and phenobarbital (30 to 60 mg) are commonly used to abort an asthmatic attack, but this combination is less effective in management of a fully developed asthmatic paroxysm. Aminophylline (0.25 to 0.5 Gm) may be added to the combination of ephedrine and phenobarbital. During a period of time when the patient is most likely to develop asthma, ephedrine, phenobarbital, and aminophylline (APE) may be given three or four times a day.

Smoking is undesirable in asthmatics, as are obesity, excessive exertion, fatigue, and dietary indiscretion.

ALLERGIC SKIN DISEASE

There are many dermatologic manifestations of allergic reactions, including urticaria, angioedema, contact dermatitis, erythematous rashes, eczematous eruptions, and others. These lesions, when attributable to immunologic processes, are divisible into those related to delayed hypersensitivity and to immediate hypersensitivity, as discussed previously. Urticaria, angioedema, and many erythematous lesions usually are attributable to immediate hypersensitivity reactions, whereas contact dermatitis and possibly many instances of eczematous dermatitis are attributable to delayed hypersensitivity reactions. Histopathologic examination of allergic skin lesions generally reveals findings which may differentiate reactions associated with immediate or delayed hypersensitivity. Vasculitis, edema, and polymorphonuclear or eosinophilic cellular response are most characteristic of urticaria and erythematous lesions, whereas mononuclear cells predominate in lesions such as contact dermatitis.

At times an antigen may induce and elicit both immediate and delayed hypersensitivity, and upon contact, ingestion, or injection of the antigen the allergic person may experience urticaria and eczematous dermatitis.

Urticaria, angioedema, contact dermatitis, and erythematous rashes are the principal forms of allergic reactions in which the skin may be the major or only site of involvement. Many other types of skin lesions, however, are attributable to systemic allergic disease, as illustrated by those seen during drug reactions. Erythema nodosum, erythema multiforme and its variants, exfoliation, bullae, purpura, "fixed" drug eruptions, photosensitivity, necrosis, and other types of skin lesions are seen in which an allergic reaction has been found or is thought to be responsible. Petechiae, erythema nodosum, erythema multiforme, and urticaria are observed in patients with infection and have been related to hypersensitivity reactions to microbial antigens. Certain types of supposed systemic immunologic disease such as systemic lupus erythematosus, dermatomyositis, rheumatic fever, and scleroderma also are characterized by skin lesions thought to be allergic. These special types of systemic disease associated with probable allergic skin reactions are discussed separately elsewhere.

Contact Dermatitis. See p. 1926.

Urticaria. Urticaria (hives) is characterized by white or red evanescent wheals, papules, or macules that are usually surrounded by erythema and are pruritic. They may be localized or generalized, but commonly appear in areas of skin covered by clothing. Urticaria also may occur in mucous membranes such as stomach and mouth, and frequently is accompanied by eosinophilia. Immediate hypersensitivity is the principal immunologic mechanism responsible for urticaria, as illustrated by the frequent occurrence of hives in serum sickness. In addition, urticaria often occurs in combination with hay fever and allergic asthma. Emotional tension, increased heat, and physical exercise may exaggerate the urticarial reaction.

Urticaria can be induced by histamine and acetylcholine, and there is good evidence indicating that liberation of histamine during an allergic reaction is responsible for hives.

Urticaria may occur from ingestion, inhalation, injection, or contact with the offending antigen by the allergic person. Foods and drugs frequently are responsible, but hives also have been related to a great variety of inhalants and contactants, such as pollen, dander, dust, feathers, and wool. The responsible antigen may be detected as in other allergic diseases by a historical dissection of the occasions when symptoms occur, by skin test, or by elimination diets.

Many instances of urticaria are chronic and cannot be related to a recognizable antigen. Occasionally parasitic infestation, such as trichinosis and echinococcosis, or bacterial infection can be associated with hives, but more often the cause of

chronic urticaria will remain undetermined. Chronic idiopathic urticaria has been attributed to nervous tension or neurosis, and this may explain some cases but other causes should be examined. A relationship has been shown occasionally between thyroid and other endocrine disorders and urticaria, but this association remains somewhat vague.

If a specific cause of urticaria is detected, it should be corrected or the antigen eliminated from the patient's environment. Acute symptoms usually can be relieved with antihistamine drugs, but occasionally adrenal cortical steroids may be needed. Intramuscular epinephrine (0.2 to 1.0 ml of a 1:1,000 aqueous solution) can provide prompt relief of symptoms in most instances. Chronic urticaria of undetermined cause ordinarily is quite refractory to treatment, and many of these patients may require psychiatric assistance. Prolonged use of adrenal cortical steroids in chronic urticaria is undesirable.

Angioedema is characterized by edema of the eyelids, lips, external genitalia, and the mucous membranes of the mouth, tongue, or gastrointestinal tract. The swellings may be localized to one area or may be diffuse, and commonly are accompanied by urticaria elsewhere. When the respiratory tract is involved the patient may have laryngeal edema with hoarseness, stridor, cyanosis, and, rarely, death.

Generally, angioedema is attributed to allergy to foods, and shellfish very commonly are incriminated. In addition, the reaction may occur from the many antigens responsible for urticaria. A rare form of angioedema is familial.

The treatment of angioedema is the same as for urticaria. If respiratory tract obstruction occurs, tracheotomy may prove lifesaving.

233 SERUM SICKNESS AND RELATED DISORDERS

Ioan L. Bennett, Jr.

Definition. Serum sickness is a systemic illness which occurs in certain susceptible individuals as a reaction to the administration of foreign serum or serum products. Common manifestations are fever, skin eruptions, lymphadenopathy, edema, and arthralgias. An indistinguishable clinical picture can result from drug hypersensitivity; indeed the syndrome is now caused more frequently by drugs than by serum products.

Etiology and Pathogenesis. Serum sickness was first recognized when the use of immune horse serum for prophylaxis and therapy of diphtheria became widespread. With advances in chemotherapy, serum is used less and less frequently, being limited for the most part to diphtheria, tetanus, gas gangrene, envenenation by reptiles, and rabies. For reasons not entirely clear, transfusion of blood is occasionally followed by serum sickness. While "raw" or whole serum is more likely to elicit a reaction, purified fractions are also capable of producing illness. The incidence and severity of serum sickness increase with dosage of the antigen.

The development of serum sickness is dependent upon an antigen-antibody reaction. An individual given an initial injection of serum will develop antibody within about 1 week and, presumably, the reaction (precipitation) of antibody and the remaining antigen leads to the illness. The onset of symptoms coincides with the appearance of antibody, disappearance of circulating antigen, and a sharp fall in serum complement. An individual previously exposed to an antigen develops antibody sooner (anamnesic or booster response) and illness is earlier in onset. Depending upon the degree of prior sensitization, a severe reaction may occur within minutes or hours.

Apparent relapses or recurrences of serum sickness are not unusual. When it is remembered that serum is not a single antigenic substance, it is clear that such a course results from a series of reactions to different antigenic components of the injected material.

The questions of the mode of injury to tissue, the release of histamine, serotonin, acetylcholine, etc., by antigen-antibody union are discussed on p. 1258. The elicitation of illness by nonprotein drugs undoubtedly involves immunologic mechanisms also. These are discussed on p. 1270.

Pathology. Serum sickness is rarely fatal. However, examination of tissues of patients dying of other causes during or shortly after an episode of serum sickness often shows lesions indistinguishable from those of polyarteritis nodosa. Similar lesions

are readily produced in rabbits by injection of foreign protein. This experimental finding is one of the several factors that have led to the idea that hypersensitivity may be important in the etiology of polyarteritis nodosa, rheumatic fever, systemic lupus erythematosus, and other diseases characterized by vascular damage.

Manifestations. After an incubation period of 4 to 10 days (it may be much shorter in sensitized individuals or can be as long as 21 days in others) there is the onset of *pruritus* followed shortly by *rash*. The rash may be any form of erythematous, morbilliform, or petechial eruption, but by far the commonest is urticaria. Often, the skin lesions appear at the local site of injection of the serum several hours before the rash becomes generalized. *Lymphadenopathy*, most prominent in the area draining the injection site, is usual as is *edema* of the face, lips, eyelids, or, rarely, the glottis. There are *fever*, *myalgia*, mild or severe *arthralgias*, *headache*, *nausea*, and *vomiting*. Other manifestations include abdominal pain, diarrhea, and cardiac arrhythmias.

The most disabling complications of serum sickness are neurologic disorders which occur in a minority of cases. The usual syndrome observed is a unilateral mononeuritis involving the shoulder girdle or arm with weakness and sensory deficit. Isolated facial palsy occurs and, occasionally, there may be extensive polyneuritis or meningoencephalitis, but these are rare.

Laboratory Findings. There is usually a mild peripheral polymorphonuclear leukocytosis, and the bone marrow shows an increase in plasma cells. Eosinophilia is not a feature of classical serum sickness, but it occasionally accompanies the drug-induced syndrome. The urine may contain protein, casts, and erythrocytes. Electrocardiograms sometimes show transient conduction defects. Slight pleocytosis in the cerebrospinal fluid is frequent even in the absence of demonstrable neurologic dysfunction.

Course. Serum sickness is a benign, self-limited disease which subsides within 1 to 3 weeks. In patients with neuropathy, residual weakness may require several weeks to abate, but complete restoration of function is the rule. Rare deaths from edema of the glottis are recorded, but a fatal outcome is more often a result of the intercurrent disease of the patient.

Treatment. Urticaria usually responds to small doses of epinephrine and can be controlled with ephedrine and antihistaminics. Local application of calamine is permissible but usually unnecessary. Contrary to early statements, joint pains are usually relieved promptly by aspirin or other salicylates.

For severely ill and uncomfortable patients, ad-

renal steroids offer prompt relief, and the great efficacy of these compounds has led to their increasing use for symptomatic relief. They need to be given for only 4 to 7 days in most patients.

Tracheostomy is sometimes needed for sudden respiratory obstruction by edema, and equipment for this procedure should be at hand during the early stages of the disease. Adrenal steroids relieve incipient obstruction promptly.

In patients who have developed serum sickness as a result of prophylactic administration of tetanus or diphtheria antiserum, active immunization with toxoid should be initiated before release from medical care to avoid later recurrence of the same problem.

Anaphylaxis. Occasional patients given an injection of serum, of skin-test antigen, or a drug will become profoundly ill and may collapse and die within minutes. There is often asthmatic wheezing and cyanosis at the onset of illness. This type of severe reaction closely resembles and, very probably, is the human counterpart of anaphylactic shock in lower animals. Because it can occur in individuals with no prior history of hypersensitivity and because fatalities have followed the injection of tiny amounts of serum for the purpose of determining a patient's state of sensitization, prevention is a very difficult matter. Perhaps the most important step in reducing the incidence of this tragic disorder is for the physician to remember that no serum product or drug should be given to any patient without clear indications. While most severe reactions occur after parenteral administration of the antigen or drug, fatalities have also been reported after oral ingestion.

Treatment consists of the intravenous or intracardiac administration of epinephrine and vigorous support of respiration and circulation. Adrenal steroids can be given parenterally but are no substitute for vasopressors, positive pressure oxygen, etc. When the injection site permits, a tourniquet may be applied to slow absorption.

Arthus Reaction. When experimental animals are sensitized to foreign serum or other proteins, reinjection of antigen into the skin often elicits transient erythema and edema, similar to a "positive" skin test in man. If animals are highly sensitive or if the dose of antigen is large, the skin lesion may progress to hemorrhage and necrosis with eventual ulceration and scarring. This irreversible tissue damage after local application of antigen in a sensitive animal is the classic *Arthus phenomenon*. Rarely, a similar type of hemorrhagic necrosis occurs at sites of injection of serum or drugs in man. These Arthus-like reactions are unusual, however, and are far outnumbered by inflammations at injection sites attributable to the intrinsic irritating properties of a drug, to hemorrhage in patients with hemophilia,

thrombocytopenia, or drug-induced coagulation defects, or to secondary pyogenic infection. Until these disorders have been ruled out, an Arthus reaction should not be invoked as the cause of tissue damage at the point of inoculation.

Shwartzman Reaction. Appropriately timed intradermal injections of bacterial endotoxins (see p. 925) or endotoxins in combination with various other substances can elicit in rabbit skin a type of hemorrhagic necrosis that resembles the Arthus reaction. However, this so-called *Shwartzman reaction* is independent of antigen-antibody union. The mechanism of the reaction is not clear, but it is not, in the immunologic sense, an allergic or hypersensitivity phenomenon although it is sometimes erroneously so classified. Numerous attempts have been made to demonstrate the importance of this reaction in the pathogenesis of human diseases including peptic ulcer, acute pancreatitis, and focal reactions in tuberculosis, but it remains, for the most part, a dramatic laboratory phenomenon. The confluent purpura of meningococcemia comes closest to being a human counterpart of the Shwartzman reaction.

234 REACTIONS TO DRUGS

Leighton E. Cluff

The increase in allergy to drugs parallels the growing use of pharmaceutical agents in the management of disease. With the continual introduction of new drugs, this problem can be expected to become even more serious.

Definition. Classification of a drug reaction is not always easy, but undesired responses to thera-

peutic agents have certain specific features which facilitate their characterization. Nearly all drugs can elicit pharmacologic effects other than those for which they are administered, and when these appear they are referred to as *side effects* or *toxic effects*. Some patients exhibit unusual susceptibility to the pharmacologic actions of a drug and are said to have an *idiosyncrasy*. In addition, reactions not explained by the pharmacologic properties of a drug and, therefore, indicative of altered reactivity of the patient are termed *allergic*. Side effects, as a rule, are intensified by increasing dosage or cumulative action, and readministration is not associated with increased reactivity of the patient. For example, nausea, hyperpnea, and tinnitus in a person given large doses of aspirin are side effects, and reduction in dosage will usually alleviate the situation. The occasional patient who displays these symptoms after taking a small amount of aspirin has an idiosyncrasy to the drug. However, if ingestion of aspirin is followed by bronchial asthma or urticaria, reactions not explainable by the drug's pharmacologic action, the patient is allergic to it. This type of reaction is likely to be associated with symptoms commonly ascribed to hypersensitivity (rash, asthma, pruritus, arthritis, fever, leukopenia, etc.), frequently recurs promptly on readministration of the drug, and is not closely dependent on dosage or cumulative action.

The clinical importance of differentiating side effects, idiosyncrasy, and allergy relates, of course, to the hazard of readministration of a drug or its probable safety in lower dosage.

Etiology. Allergy to drugs may be attributed to immediate or delayed hypersensitivity reactions. Most pharmacologic agents, however, are incapable of initiating an immunologic response by themselves, and it is thought that the actual antigen is a conjugate of the drug or its derivatives with serum or tissue proteins. Under such circumstances, the drug would act as a hapten, nonantigenic by itself, but conferring antigenic specificity to the protein, and capable of combining with the antibody or reacting with cells of the sensitized person in response to the drug protein conjugate. Many drugs are bound by body proteins, and there is experimental evidence that the ability of chemical compounds to elicit allergic contact dermatitis can be correlated with their affinity for sulfhydryl containing proteins of skin. Practically all drugs bind to serum protein, particularly albumin, following absorption, but there is little to suggest that such protein-drug conjugates are important in drug allergy. Other tissue proteins also may bind drugs, but those specifically responsible for rendering a chemical antigenic are not known. Furthermore, the administered drug may be of less importance in inducing an immunologic response than its degrada-

tion products. For example, recent observations show that penicillic acid and penicilloic acid, degradation products of penicillin, may be responsible for most instances of penicillin allergy.

Serum antibody has been demonstrated in some persons with drug allergy involving cellular elements of blood, such as in agranulocytosis, hemolytic anemia, and thrombocytopenia. In other types of drug hypersensitivity, however, the usual techniques for demonstrating antibody ordinarily yield negative findings. Precipitation, hemagglutination, or complement fixation tests with a patient's serum may be negative, and direct intradermal or passive transfer tests of the Prausnitz-Kustner type are often unrevealing. In addition, demonstration of agglutination by serum of erythrocytes sensitized with a drug such as penicillin may fail to differentiate the allergic from the nonallergic individual. These results, however, are more indicative of the inadequacy of present methods of testing than an argument against an immunologic basis for hypersensitivity to drugs. The lack of consistently effective testing methods, of course, is a great handicap to clinical investigations of drug reactions.

Most types of allergic reactions to drugs do not appear to be familial; however, it has been suggested that anaphylaxis may occur more commonly in persons with other allergic disease such as hay fever, asthma, or urticaria. Certain types of underlying disease, however, may possibly predispose to the development of drug allergy. For example, patients with systemic lupus erythematosus probably experience more drug allergic reactions than do normal individuals. Similarly, patients with severe infection such as pneumonia and septicemia have allergic reactions to drugs more commonly than persons with less intense infection such as latent or primary syphilis. Furthermore, the patient acquiring an allergic reaction to one drug often will develop at the same time allergic reactions to other drugs he is receiving, but the manifestations of the reactions may differ.

Manifestations. The commonest manifestations of allergy to drugs are no different from hypersensitivity reactions of other types, and include rashes, asthma, and the symptoms of serum sickness (see Table 234-1). These are easily recognized clinically as allergic in origin. Other features of drug allergy are sometimes less easily characterized, however. The tabulation (see Table 234-1) of common drugs and reactions which they may elicit includes some effects that may not be allergic at all. A few examples of allergic drug reactions will illustrate the variations seen with different pharmacologic agents.

Skin. Morbilliform, urticarial, and maculopapular rashes are the most common skin reactions, but many others are observed, including vesicular, bul-

lous, exfoliative, eczematous, and purpuric eruptions. Pruritus is frequent. Although the type of skin lesion usually will not aid in identifying the causative drug, there are certain skin reactions which are somewhat specific. Erythema multiforme or nodosum is particularly seen in allergy to Dilantin, bromides, iodides, trimethadione, and sulfonamides. "Fixed" drug eruptions are most frequently due to amidopyrine, phenolphthalein, or Atabrine. Photosensitization during drug therapy occurs characteristically with chlorpromazine, phenothiazine, sulfonamides, and tetracycline derivatives.

Fever. Fever may be an isolated manifestation of drug allergy, and at least 35 pharmaceuticals in common use can produce a febrile reaction, including most antibiotics and chemotherapeutic agents. However, the tetracycline derivatives are uncommon causes of drug fever, and digitalis has rarely, if ever, been incriminated as the cause of a pyrogenic reaction. Elevation of temperature can appear abruptly after initiation of treatment or develop in a stepwise fashion during or after the second week of drug administration. Drug fever is often associated with chills and constitutional symptoms and can be accompanied by leukocytosis. Discontinuation of therapy usually results in defervescence within a very few hours, although several days may be required for return of temperature to normal.

Blood. Changes in the formed elements of the blood are rather common during drug allergy and may have no specificity. Some drugs have been found to have limited or no effects on the blood, while others produce specific abnormalities. For example, penicillin has never been incriminated as a cause of serious hematologic abnormalities. In therapeutic doses, acetanilid is probably not a cause of anemia, agranulocytosis, thrombocytopenia, or aplastic anemia; in high dosage, however, it may produce leukocytosis, methemoglobinemia, and acute hemolysis. Methemoglobinemia also occurs with antipyrine, nitrites, sulfonamides, primaquine, and pamaquine, but this reaction is probably not allergic in origin. Barbiturates, salicylates, and paraminosalicylic acid rarely, if ever, produce agranulocytosis. Eosinophilia can accompany allergic reactions of many types, but occurs with such frequency as an isolated finding during therapy with streptomycin or nirvanol that it has no significance in these instances. Lymphocytosis is common in patients receiving Dilantin and nirvanol, but polymorphonuclear leukocytosis may be found in individuals taking Dilantin or atropine. Recent studies of the erythrocyte abnormality responsible for the acute hemolytic anemia induced by primaquine, sulfonamides, and nitrofurans in certain individuals indicates that what was thought to be drug allergy is actually a genetically determined idiosyncrasy

(see p. 1291). Jaundice and acquired hemolytic anemia due to pharmacologic agents are discussed elsewhere (p. 1289).

Nervous System. A variety of neurologic manifestations may appear during drug therapy, but in the majority of instances there is little evidence to incriminate allergy as a cause. The commonest reaction, by far, is delirium, seen particularly with digitalis, atropine, thiocyanates, and sedatives. Other drugs which produce adverse effects upon the nervous system (ranging from paresthesias and peripheral neuritis to deafness) are streptomycin, hydralazine, chlorpromazine, Diamox, isoniazid, polymyxin, and neomycin.

Others. Nausea, vomiting, and diarrhea are exceedingly common drug reactions. In addition, abdominal pain in the absence of other symptoms may be produced by quinidine, chlorpromazine, and primaquine. Albuminuria and cylindruria occur particularly with heavy metals, bacitracin, and polymyxin. Dilantin, chloral hydrate, sulfonamides, trimethadione, Phenurone, colchicine, and thiocyanate occasionally produce renal dysfunction, probably by direct toxic action. Hypersensitivity to sulfonamides has resulted in acute hemorrhagic nephritis.

Histologic lesions indistinguishable from those of polyarteritis nodosa have been found in the tissues of patients who have experienced allergic reactions to iodides, Dilantin, sulfonamides, and penicillin. Manifestations of systemic lupus erythematosus have appeared during therapy with gold or hydralazine.

Anaphylaxis may follow the parenteral administration of a variety of drugs, but the agent most seriously incriminated at present is penicillin. Development of anaphylaxis has been reported after oral ingestion of the drug, but this is exceedingly rare.

The incidence of drug allergy is not high and is particularly related to the frequency with which a pharmacologic agent is used clinically. For this reason, probably, these reactions are now often observed with antibiotics. However, the incidence of allergic reaction also varies with the agent, and with some drugs may be as high as 10 per cent.

Treatment and Prophylaxis. Allergic reactions to drugs usually subside promptly when the agent is discontinued. For reasons that are not understood, however, the reaction occasionally persists for prolonged periods in spite of withdrawal, recurrent urticaria for many months after a penicillin reaction is a common example. The management of serum sickness is described elsewhere. In the event of persistent or severe manifestations of drug allergy, the use of adrenocortical steroids is indicated. Adrenal steroids, antihistamines, and epinephrine are usually ineffective in alleviating reactions due

to idiosyncrasy or side effects of a drug. Reactions of this type are best managed by administration of other drugs with appropriate pharmacologic actions, i.e., sedatives for excitability, stimulants for depression, etc., and by withdrawal of the offending drug.

Although it is not possible to predict the occurrence of drug allergy in a patient, the fact that hypersensitivity to drugs may be commoner in individuals with other allergic reactions makes it reasonable to inquire about this before initiation of treatment with any agent. A specific history of hypersensitivity to a given drug contraindicates its readministration unless the clinical situation is serious. In a number of instances where it has been judged necessary to prescribe a drug to which a patient is known to be allergic (e.g., penicillin for bacterial endocarditis), the concomitant administration of adrenal steroids has completely suppressed the manifestations of hypersensitivity.

Although it is commonly said that sensitivity to a drug will subside if its administration is continued, this is not a regular occurrence and should not be accepted as a basis for further therapy with the incriminated agent.

Section 1: The Hematopoietic System

INTRODUCTION

M. M. Wintrobe

The hematopoietic system includes the circulating blood, the bone marrow, the spleen, and the lymph nodes, supplemented by the reticuloendothelial cells scattered about the body. The liver, through the presence there of reticuloendothelial cells, as well as by reason of other functions, is also intimately concerned in blood formation and destruction. Since the function of the red corpuscles is to hold in nondiffusible form the pigment, hemoglobin, essential for the transport of oxygen, any alteration in the quantity of red corpuscles or in their hemoglobin content affects the function of all the organs of the body. An important function of the leukocytes is to take part in the reaction to injury, particularly in the defense against infection. The blood platelets are concerned in maintaining the integrity of the vascular endothelium and in the clotting of blood. The blood plasma, which carries these three types of corpuscles, is also the medium for the transport of many substances concerned in the metabolism of the organism.

Since the blood and its constituents are so intimately related to the body as a whole, much will be found concerning the blood in various chapters in this book and particularly in those in Part Two. In regard to the red blood corpuscles, attention should be called especially to Chap. 23 (Pallor and Anemia), where the synthesis and the destruction of hemoglobin and the classification, pathogenesis, and management of anemia are considered, as well as the symptomatology and methods of study of a patient with anemia. The platelets, the phenomenon of coagulation, and the various ways in which bleeding is produced receive attention in Chap. 24 (Bleeding).

In the present section, disorders of the hematopoietic system will be considered. It is evident that such disorders make themselves known in a variety of ways. These may be such that discovering their cause may tax the acumen of even the most discerning physician. In the main, however, they are characterized in part or whole by symptoms and signs such as pallor, cyanosis, jaundice, bleeding, or enlargement of the lymph nodes or spleen. A thorough understanding of these manifestations of disease is a prerequisite to the correct differentiation as well as the effective treatment of the disorders of the hematopoietic system.

The approach to the patient suspected of having a hematopoietic disorder is discussed, therefore, in Part Two under headings such as Pallor and Anemia, Bleeding, and Enlargement of Lymph Nodes and Spleen. Although, in the subsequent pages, descriptions of the various recognized disorders of the hematopoietic system will be found and their treatment discussed, it is urged that the reader confronted with a problem, for example, of anemia, first study Chap. 23, because he will find there a discussion of anemias in general and he will thereby make his way more readily through the pages that follow or, for that matter, through other sections in this textbook. The same is true, in principle, if the problem is one of bleeding or lymph node enlargement or splenomegaly.

235 THE ANEMIAS

M. M. Wintrobe

POSTHEMORRHAGIC ANEMIA

Anemia resulting from blood loss may have developed suddenly because of the rapid loss of a large quantity of blood, or it may have come about very gradually over a period of many months or even years. Obviously there are also many possible variations between these two extremes. The causes of posthemorrhagic anemia are numerous and the manifestations differ widely, the latter depending in part on the nature of the underlying disorder and in part on the quantity and speed of the blood loss. It is convenient to consider acute and chronic posthemorrhagic anemias separately because their manifestations and, in certain respects, their treatment differ so greatly. It should be realized, however, that these two syndromes represent two extremes depending, in the main, on the same underlying defect, and that in practice variations will be encountered which represent all stages between these extremes.

Acute Posthemorrhagic Anemia

Etiology. Trauma, the rupture of a peptic ulcer or an ectopic pregnancy, and bleeding in connection with hemophilia or purpura hemorrhagica are examples of the widely varied possible causes of acute blood loss. They indicate that the blood loss may be

external and recognizable at once, or internal and, consequently, sometimes not readily discovered.

Symptomatology. The rapid loss of blood leads to reduction in blood volume, and the clinical manifestations are mainly circulatory. If the blood loss is great, "acute posthemorrhagic shock" develops (see Chap. 13). If the hemorrhage is visible to the patient, whether the amount of blood lost is great or small, symptoms may arise from the psychic effect of such bleeding. Generally speaking, symptoms are likely to appear sooner and are more pronounced in relation to the amount of blood lost when the bleeding is external than when it is not recognizable by the patient. The manifestations of anemia in general have been discussed already (p. 207). In addition, the symptoms of the underlying disorder may be present as well.

Blood Picture. Polymorphonuclear leukocytosis with the appearance of immature forms ("shift to the left") is the first discernible change. An increase in platelets often takes place as well. The anemia may not be apparent at once since, at first, plasma is lost as well as red corpuscles, so that the ratio of cells to plasma remains the same. As fluid is drawn from the tissues to restore the blood volume, anemia becomes apparent. This is normocytic at first. Blood loss in an otherwise healthy organism, however, profoundly stimulates the bone marrow. This becomes hyperplastic, and immature corpuscles are liberated in larger numbers than usual. Reticulocytosis ensues, polychromatophilia is found, and even nucleated red corpuscles find their way into the blood. At this stage the anemia may be macrocytic since the immature cells are larger than the older forms. Reticulocytes begin to appear within 48 hr following a brisk hemorrhage and may continue to increase for several more days. A persistent reticulocytosis, forming a plateau-like curve, suggests that bleeding is continuing, for cessation of hemorrhage is marked by quick restoration of physiologic balance with rapid regression of the signs of stimulated hematopoiesis. If the iron stores of the body are good and the blood loss has not been extreme, iron deficiency does not occur and hypochromia is slight or absent. When the drain on iron is greater than can be readily replenished, iron deficiency begins.

When the acute hemorrhage is internal, destruction of the blood and absorption of the products may lead to an increased excretion of urobilinogen in the urine and stools, and, rarely, even slight bilirubinemia may be found. Bowel hemorrhage is often associated with an increase in the blood urea nitrogen level.

Diagnosis. When acute hemorrhage is not evident, such signs as pallor, faintness, restlessness, sweating, and palpitation should lead to a search for hemorrhage. If the subject is recumbent, much blood may be lost before these signs appear. They

can be brought out by tilting the patient to the erect position. Late signs of acute blood loss are air hunger, thirst, and a falling blood pressure.

Prognosis. The amount and rapidity of the blood loss, the acuteness of the physician in discovering it, the availability of blood for transfusion, and the accessibility of the site of bleeding are the important considerations.

Treatment. Stopping of the hemorrhage and restoration of the blood volume to normal, preferably by transfusions of whole blood, otherwise by administration of plasma or other fluids, are the essentials. Speed in restoration of blood volume is more important than whether plasma or whole blood is used. If the blood loss has been great and the blood volume is profoundly reduced, multiple portals should be used for administration of blood, and even intraarterial administration may be advisable. Fluids by mouth (unless the bleeding is from the upper portion of the alimentary tract) and by hypodermoclysis are valuable adjuncts, as are rest and quiet, induced by morphine if necessary. Following the acute phase, a good diet containing meat, fruit, and vegetables affords the proteins and vitamins needed for erythropoiesis. Iron can be given in the form of ferrous sulfate (0.2 to 0.4 Gm t.i.d.) but is not needed in previously normal individuals unless blood loss has been great.

Chronic Posthemorrhagic Anemia

This refers to that state in which blood loss has produced a chronic anemia, and a deficiency of substances necessary for blood formation has developed. Although the factors essential for erythropoiesis are many, the chief deficiency resulting from chronic blood loss is that of iron. The manifestations of chronic posthemorrhagic anemia can therefore be discussed in the section which follows.

IRON-DEFICIENCY ANEMIA (Hypochromic Microcytic Anemia; Idiopathic, Chronic, or Nutritional Hypochromic Anemia; Chlorosis, Chlorotic Anemia, Chloranemia)

Etiology. Iron is normally obtained by digestion of food and is absorbed chiefly in the upper portion of the gastrointestinal tract. This is aided by the acid secretion of the stomach. The absorbed iron is utilized for hemoglobin formation, as well as for the production of myoglobin and other enzymes. Normally a large reserve is stored in the liver, spleen, and other tissues. The total iron store in man which is available for blood formation has been estimated to amount to 1.2 or 1.5 Gm. Once absorbed, iron is conserved tenaciously. The amount lost per day by the normal adult male has been estimated as approximately 1 mg.

Any circumstance which leads to a greater demand on the iron stores of the body than can be supplied results in iron deficiency. In logical order, the possible factors leading to iron deficiency are (1) insufficient iron in the diet, (2) impaired absorption, (3) increased requirements, and (4) loss of blood. Of these, the chronic loss of blood by hemorrhage is by far the most common factor in the development of iron deficiency. Excessive menstruation and occult bleeding from the gastrointestinal tract (peptic ulcer, esophageal varices, hookworm infection, etc.) are the most common types of bleeding which may result in iron deficiency, since the former is but an exaggeration of a physiologic process and may thus receive little attention, while the latter may pass unnoticed for a long time.

Impaired absorption of iron is rarely an important factor in the development of iron deficiency, even though various influences favor or inhibit the availability and absorption of iron. Thus, a high level of calcium in the diet diminishes the formation of insoluble iron phosphates and favors absorption of iron, but excess calcium inhibits iron assimilation. Ascorbic acid favors iron assimilation, probably by promoting the reduction of ferric iron in food to the ferrous form. Although the gastric hydrochloric acid favors ionization and thus absorption, many persons are encountered in whom achlorhydria has existed for years without iron deficiency developing. Chronic diarrhea, however, is of more importance. Certainly iron deficiency may be encountered in spite.

Deficiency of iron in the diet alone is rarely a cause of iron deficiency except in infants receiving a milk diet exclusively, and occasionally in elderly people who, although they have had no blood loss for many years, have depleted their stores by consuming a diet very low in iron.

In children and adolescents the iron needs for growth are very important, and it is largely because of the demands made by the ever-expanding blood volume that infants receiving an unsupplemented diet of milk develop iron deficiency. In older children and adolescents, poverty or faulty habits may contribute to the mounting deficiency by causing consumption of a diet too low in iron to supply the needs. In girls, the menstrual loss of blood accentuates this deficiency. Normal menstruation results in an average loss of 0.5 to 1.0 mg iron per day. Chlorosis, the "green sickness" of the last century and before, was probably no more than iron deficiency in adolescent girls in whom low dietary iron was insufficient to meet the needs. In adult women the iron requirements during pregnancy and lactation are factors which may lead to the development of iron-deficiency anemia. Pregnancy results in a net deficit of iron of approxi-

mately 1 mg per day, lactation about 0.5 mg per day. Often these circumstances are superimposed on a state of gradually increasing iron depletion which may have had its beginning in adolescence. The ultimate combined effect of chronic loss of blood, increased demands, and faulty diet may not become clearly manifest until thirty to forty-five years of age, the period in which the *chronic hypochromic anemia* of women is most often seen. It is of interest that in such individuals certain *constitutional features* similar to those encountered in pernicious anemia may be observed, such as early graying of the hair and achlorhydria.

Since so little iron is excreted normally, iron deficiency develops in the adult male only from loss of blood or, rarely, from dietary deficiency or impaired absorption which has existed over a period of many years. In the male, ulcerative lesions in the gastrointestinal tract are by far the most likely causes of long-continued, undetected loss of blood.

Symptomatology. The symptoms are those common to all chronic anemias and may include a variety of vague gastrointestinal complaints, such as anorexia, capricious appetite, or heartburn and, more rarely, sore tongue, sore mouth, and dysphagia (Plummer-Vinson syndrome); or palpitation, dyspnea, and edema about the ankles; or neuralgic pains, vasomotor disturbances, or numbness and tingling. Menstrual disturbances are common—menorrhagia, irregularity of flow, or even phases of amenorrhea.

A tired, lifeless appearance; pallor; inelastic and often dry and wrinkled skin, sometimes with a brownish hue; dry and often scanty hair; and blue scleras are found in cases of long standing. In many, some degree of papillary atrophy of the tongue, slight cardiac enlargement, functional systolic murmurs, and a palpable spleen are discernible. When the deficiency is severe, the nails may be flattened, longitudinally ridged, or even concave (koilonychia), and may break easily. The sore tongue, dysphagia, and changes in the hair, nails, and skin may occur in iron deficiency prior to the development of anemia.

Blood Picture. A good blood smear will reveal thin, pale red corpuscles poorly filled with hemoglobin. In some cases these may be mere rings. Tiny microcytes, "target-like" cells, elliptic cells, and bizarre poikilocytes are also found, as well as a certain proportion of normally filled corpuscles. The anemia is hypochromic and microcytic. Only in this type of anemia is a substantially reduced mean corpuscular hemoglobin concentration (MCHC) encountered (less than 30 per cent). This hypochromia is more significant than the microcytosis, although the latter may be extreme (mean corpuscular volume 55 to 75 μ m). The red corpuscle count may be normal or nearly so, or even greater than normal, while the hemoglobin

and volume of packed red corpuscles are greatly reduced. The leukocyte count is normal or slightly reduced, and a slight thrombocytopenia may exist.

The bone marrow is hyperplastic and contains an excessive number of normoblasts.

Diagnosis. The symptoms are naturally varied, since iron deficiency may result from a large variety of causes. When iron depletion is only moderate in degree, the changes in the blood may not be striking. In more advanced cases, adequate examination of the blood should make it clear that hypochromic microcytic anemia exists. This type of anemia is most often due to lack of iron. Experimentally a similar anemia is observed in copper and in pyridoxine deficiency, but in man such deficiencies are exceedingly rare, if they occur at all. Metabolic disorders involving these substances have been described, however. Thus, there is a syndrome in infants and young children in which low serum copper values and hypoproteinemia accompany a hypochromic microcytic anemia which responds to iron therapy. Again, a refractory, microcytic hypochromic anemia accompanied by hyperferremia and, in a few instances, by splenomegaly and hepatomegaly has been observed in eight cases which responded to the administration of pyridoxine in large quantities. Other instances of refractory hypochromic microcytic anemia have been described, such as "hereditary, sex-linked (?) anemia," which may be related to the pyridoxine-responsive type, but these are all exceedingly rare. The only form of hypochromic microcytic anemia which is not extremely rare and which may be mistaken for that due to iron deficiency is thalassemia (p. 1801). Consequently, the discovery of hypochromic microcytic anemia usually calls for a search for causes of iron deficiency and, in particular, requires a thorough search for sources of blood loss.

Prognosis. This is excellent in so far as the possibility of relieving the anemia is concerned. The prognosis otherwise depends on the character of the contributory causes.

Treatment. Only in iron-deficiency anemia is iron therapy of value. Here the administration of *ferrous sulfate* or *ferrous gluconate* is followed by a reticulocyte response, and subsequently rapid red corpuscle regeneration occurs. Gastric irritation is less likely to occur if tablets of 0.2 Gm are taken on a full stomach. To allow the patient to become accustomed to it, at first a total of 0.4 Gm is given per day, but this may be increased to 1 Gm. In addition to iron therapy, a good diet containing meat, fruit, and vegetables is to be recommended, and any underlying or associated disorder should be corrected. Transfusion of blood is rarely if ever needed, even in the most anemic patient, and free hydrochloric acid is not required even if achlorhydria is present. Failure to respond to oral iron ther-

apy, necessitating intravenous administration, has been described but is exceedingly rare.

MACROCYTIC ANEMIAS

Elucidation of the pathogenesis of pernicious anemia, even though still incomplete, has made it clear that there are a number of closely related disorders which have in common a characteristic type of anemia, megaloblastic hyperplasia of the bone marrow, and the capacity to respond to liver therapy, yeast, pteroylglutamic acid, vitamin B₁₂, or related substances. These conditions, the *megaloblastic macrocytic anemias*, must be differentiated from those instances of macrocytosis which represent increases in mean corpuscular volume from other causes, usually from the presence in the circulation of a relatively large number of immature red corpuscles appearing in response to such hematopoietic stimulants as severe hemorrhage or acute blood destruction (Table 235-1). In this second type of macrocytic anemia the bone marrow is not megaloblastic and liver, vitamin B₁₂, or folic acid therapy has no value. The clinical differentiation is usually easy.

Pernicious Anemia (Addisonian Pernicious Anemia, Addison's or Biermer's Anemia, Primary Anemia)

Definition. Pernicious anemia is a chronic disorder characterized by macrocytic anemia, megaloblastic hyperplasia of the bone marrow, gastric achlorhydria, and often glossitis and changes in the nervous system. This disorder appears to be the consequence of a permanent gastric secretory defect associated with atrophy which results in a deficiency in the body of a substance derived from food. The deficiency can be corrected by supplying a substance present in certain liver extracts which appears to be identical with vitamin B₁₂.

History. Although the disorder was described at least as early as 1823 by Combe, it was the picture given by Thomas Addison in 1855 and the comprehensive description by Biermer in 1872 which drew attention to this ultimately fatal (therefore "pernicious") anemia. The discovery of the value of liver therapy by Minot and Murphy in 1926 and the elucidation of the role of the stomach in the pathogenesis of the disorder by Castle in 1929 completely changed the prognosis of the condition and profoundly stimulated hematologic research in general.

Etiology. This disorder is very rare in persons under the age of thirty and is encountered much more frequently in light-haired, blue-eyed individuals than in the darker races or in Orientals. It is

Table 235-1. CLASSIFICATION OF MACROCYTIC ANEMIAS

I. Megaloblastic macrocytic anemias

A. Conditions responding to administration of both vitamin B₁₂ (liver extract) and folic acid

Condition	Probable pathogenesis
1. Pernicious anemia*	Deficiency of gastric intrinsic factor
2. Total gastrectomy	Removal of source of intrinsic factor
3. Nutritional macrocytic anemia	Dietary deficiency
4. Sprue, idiopathic steatorrhea	Impaired absorption
5. Resection of small intestine	Impaired absorption
6. Intestinal strictures and anastomoses	Diversion of vitamin B ₁₂ and folic acid from host
7. Fish tapeworm anemia	Diversion of vitamin B ₁₂ and folic acid from host

B. Conditions responding only, or usually, to folic acid, rather than to vitamin B₁₂

8. Megaloblastic anemia of pregnancy	Metabolic disturbance? Increased requirements?
9. Megaloblastic anemia of infancy	Deficiency of folic acid and ascorbic acid
10. "Achromic" anemia and "refractory megaloblastic" anemia	Metabolic disturbance? Complex or unusual deficiencies?
11. Anticonvulsant drugs	Metabolic antagonists
12. Amethopterin or 6MP therapy	Metabolic antagonists
13. Unusually vigorous erythropoiesis	Increased demands, low stores

II. Nonmegaloblastic macrocytic anemias

A. Acute posthemorrhagic anemia	Presence in blood of many immature erythrocytes
B. Hemolytic anemia	Presence in blood of many immature erythrocytes
C. Aplastic anemia	Unknown
D. Hypothyroidism	Unknown
E. Liver disease	Unknown

* Pernicious anemia is distinguished from the other conditions listed in that achlorhydria is always present and neurologic changes may occur.

N.B. In practice, the most common cause of what appears to be macrocytic anemia is laboratory error, most often in red corpuscle counting.

seen especially in natives of the British Isles, the Scandinavian countries, and other more northern regions, as well as in their offspring in other parts

of the world. Nevertheless, although less common, pernicious anemia is seen in Negroes.

A familial incidence is not unusual. Those affected often have turned gray prematurely, and they may have broad faces and large, bony frames. Males and females are affected about equally.

That a gastric secretory defect is a fundamental factor in the pathogenesis of pernicious anemia was suggested almost as early as the disease was recognized. It was shown later that absence of hydrochloric acid in the gastric secretion and a greatly reduced total gastric secretion (achylia) precede the development of the anemia by many years. It has also been shown that such achylia is a defect which persists in spite of successful antianemic therapy. Castle demonstrated that the significant abnormality in gastric secretion is not lack of hydrochloric acid but absence of an "intrinsic factor" which normally acts upon an "extrinsic factor" derived from food. The material so produced was regarded as leading to the formation of a substance stored in the liver without which normal hematopoiesis cannot take place. The gastric factor is thermolabile. It seems to be contained in or adsorbed to the glandular mucoprotein of the stomach. The thermostable food factor is present in meat, eggs, cereals, and other natural sources of the vitamin-B complex and is also present in liver. Desiccated hog's stomach given orally has the same hematopoietic effect in pernicious anemia as liver, and its effectiveness was assumed to be due to the interaction of the intrinsic and extrinsic factors in gastric tissue.

The discovery of vitamin B₁₂ (cyanocobalamin), a red pigment containing cobalt, and the demonstration of its therapeutic effectiveness in pernicious anemia on parenteral administration in amounts as small as 1 µg have clarified some of the puzzling aspects of the pathogenesis of this disease. Vitamin B₁₂ is also active orally if given in very large amounts (100 to 150 µg), but its hematopoietic effectiveness is greatly increased by normal human gastric juice. Vitamin B₁₂ is apparently the extrinsic factor as well as the liver factor or "antipernicious-anemia principle." The role of the gastric or intrinsic factor is simply to promote the absorption of vitamin B₁₂ from the alimentary tract, possibly by binding with vitamin B₁₂ and, in turn, being bound by receptors in the intestinal wall. Because of the absence of intrinsic factor in patients with pernicious anemia, the absorption of vitamin B₁₂ is impaired and the effects of deficiency ultimately develop.

The vitamin pteroylglutamic acid (folic acid) has been shown to produce a hematopoietic response in pernicious anemia when given orally or parenterally. It is neither Castle's intrinsic factor nor the extrinsic factor. In nature it is found in

conjugated form, as the heptaglutamate (yeast) or as triglutamate. An observation of great practical importance is that whereas the administration of liver extract or vitamin B₁₂ prevents the development or advancement of the neural manifestations of pernicious anemia, these may appear in spite of folic acid therapy.

The metabolic functions of vitamin B₁₂ and folic acid are, in the main, closely related but they are by no means fully understood. They are both concerned in the metabolic reactions which involve one-carbon fragments and thereby are important in the biosynthesis of purines, pyrimidines, and certain amino acids. Vitamin B₁₂ is also involved in the incorporation of amino acids in protein and influences folic acid metabolism in several ways. The close metabolic relationship of the two substances appears to be the reason why a deficiency of either or both results in a number of abnormalities, of which megaloblastic bone marrow is the most readily recognized. Reasons have been offered for the progress of the neural changes observed in some patients with pernicious anemia receiving folic acid therapy, but none has found adequate support.

The red corpuscles of patients with untreated pernicious anemia appear to have a shortened survival time. Thus the bilirubinemia and urobilinogenuria so characteristic of pernicious anemia would seem to be manifestations of a more rapid blood destruction, which may be the consequence of imperfect construction of the red corpuscles resulting from a deficiency of building materials. That this is not the sole explanation of the disturbance in pigment metabolism in pernicious anemia, however, is suggested by the observation that 40 per cent or more of labeled stool urobilin in pernicious anemia is not derived from circulating red corpuscles. Some of the pigment apparently comes from heme or hematin which has not been used for hemoglobin synthesis.

Pathology. The significant findings are in the alimentary tract, the bone marrow, and the nervous system. The tongue usually appears smooth and the papillae may be absent. Atrophy of the mucous membrane may be striking in the tongue and in the stomach. The changes in the stomach have been observed particularly in the fundic zone, where the parietal and chief cells are usually absent.

Appropriate staining reveals the liver as well as the spleen and kidneys to be abnormally laden with iron. In the liver this is found in the periphery of the lobules and in the Kupffer cells. There may also be fatty degeneration in the central cells of the lobules of the liver. The heavy deposit of iron is the consequence of the fault in red corpuscle formation which leads to the development of anemia;

when active blood regeneration follows therapy, the iron is used in blood formation.

The bone marrow is red and is found to be crowded with cells. Cells of the red series make up 30 to 50 per cent, rather than about 20 per cent of the cells of the marrow. The degree of hyperplasia and the degree of immaturity of the cells are roughly proportional to the severity of the anemia. The nucleated red corpuscles ("megaloblasts") differ from those found in other types of anemia in several respects. They are exceptionally large and, more significantly, the nuclear chromatin is fine and sieve-like, unlike the relatively coarse and "lumpy" material seen in normoblasts. The cytoplasm of these cells may be polychromatophilic or orthochromatic, and in a few is basophilic. Many abnormal mitotic figures may be present. At the same time, extraordinarily large leukocytes may be found in the marrow; in particular, large metamyelocytes can be seen with bizarre-shaped nuclei and peculiar staining or vacuolated cytoplasm. Megakaryocytes may be reduced in number and may be morphologically abnormal. In spite of the evidence of cellular activity, hematopoiesis is inefficient and anemia develops.

In the nervous system, degenerative changes may be found in the dorsal and lateral tracts of the cord, in the dorsal root ganglions, and in the peripheral nerves. Myelin degeneration and loss of nerve fibers occur. More rarely, changes are encountered in the brain.

Symptomatology. The onset of the disease is generally insidious. In many instances at least two of the diagnostic triad of symptoms are encountered; namely, weakness, sore tongue, and numbness and tingling in the extremities. However, other complaints may overshadow these, and the presenting clinical picture may suggest some disorder of the digestive tract because of anorexia, diarrhea, and various other gastrointestinal symptoms; it may simulate cardiac dysfunction of the anginal or the congestive failure type; or one may be led to search for some malignant neoplasm or an obscure infection. In some instances the neural involvement is so pronounced that a primary neurologic disease is considered. Even renal or genitourinary disease or a mental disorder may be simulated.

The degree of soreness of the tongue varies greatly and the involvement may be complete or patchy. The tongue may be "beefy" red when the symptoms are pronounced and is less red and smooth when they subside. The gastrointestinal symptoms vary greatly. However, one consistently found in relapse is anorexia. Symptoms referable to the circulatory system include dyspnea, palpitation, sensations of extra beats, weakness, vertigo, tinnitus, and precordial pain. Since pernicious ane-

mia often appears for the first time in the older age groups, it may be difficult to determine to what extent anemia or the degenerative changes of old age have contributed to the development of heart failure.

Pallor; a flabby rather than wasted appearance; a slight or pronounced yellowish color of the skin together with faint icterus of the scleras; a tongue which is often glazed in appearance and sometimes is red and sore; a rapid pulse with slight cardiac enlargement and often precordial hemic murmurs; in many, a spleen which is just palpable; and often a slightly enlarged liver are the chief findings outside the nervous system. In the nervous system, loss of vibratory sense in the lower extremities (not necessarily symmetric), incoordination of the lower extremities, loss of finer coordination of the fingers, signs suggestive of lateral as well as posterior spinal cord involvement, and evidence of peripheral nerve degeneration are the most common findings and may be present in all degrees from slight or none to extensive involvement. Positive Babinski response, positive Romberg's sign, disturbed position sense, spasticity, increased or diminished reflexes, and sphincter disturbances may be encountered. Minor mental disturbances (irritability, memory disturbances, mild depression) or more serious mental symptoms may develop.

Laboratory Findings. Blood. The anemia is usually more severe than the complaints and physical examination would lead one to suspect. In the blood smear, macrocytes, often oval in shape, are characteristically seen (Fig. 235-1), but there is actually a great range in the size of the cells, and in addition, many bizarre-shaped corpuscles are found (poikilocytosis). Since the abnormally large cells predominate, the mean corpuscular volume is found to be greater than normal and ranges between 100 and 160 μ (Fig. 235-2). There is a corresponding increase in the hemoglobin content of the red corpuscles (mean corpuscular hemoglobin), so that the concentration of hemoglobin in the corpuscles (mean corpuscular hemoglobin concentration) is normal. The red corpuscles in pernicious anemia is normal. The red corpuscles in pernicious anemia and in other macrocytic anemias are not "hyperchromic," but, being thicker as well as larger in diameter than normal corpuscles, they appear to be supersaturated with hemoglobin, as one looks at them through a microscope. Some degree of diffuse polychromatophilia as well as basophilic stippling is found, and occasional nucleated red corpuscles may be encountered. The most striking changes, described in classic cases, are observed only when the anemia is very severe. Since the anemia is macrocytic, the red corpuscle count is reduced more than proportionately as compared with the hemoglobin or the volume of packed red

FIG. 235-1. Drawing of a blood smear from a case of pernicious anemia in relapse. From a preparation stained with Wright's and magnified $\times 960$. Note the extreme variation in the size and shape of the red corpuscles, the large polychromatophilic red corpuscle (a), the cells containing nuclear remnants and Howell-Jolly bodies (b, c) and a Cabot ring (c), the granular red corpuscle (d), and the multisegmented polymorphonuclear leukocyte. (Wintrobe: "Clinical Hematology," 5th ed., Philadelphia, Lea & Febiger, 1961.)

corpuscles. Reticulocytes are usually within normal limits in untreated patients or, at most, do not run higher than 3 or 4 per cent.

The leukocyte count is usually lower than normal, chiefly because of a granulocytopenia. Thus, there is relative lymphocytosis. The polymorphonuclear neutrophilic leukocytes often show an unusual number of segments and may be exceptionally large. An occasional myelocyte is present in many cases. Sometimes some degree of eosinophilia is encountered. The platelets are generally reduced in number, sometimes to levels below 100,000 per cu mm, and bizarre forms, including giant platelets, may be found. When there is thrombocytopenia, the bleeding time may be prolonged, the blood clot retracts poorly, and purpura may develop.

The resistance of the red corpuscles to hypotonic saline solutions is not significantly altered. The icterus index usually ranges between 8 and 15; sometimes it is as high as 20 or 25. The average plasma bilirubin content is 1 mg per 100 ml but often is higher, and the van den Bergh reaction is "indirect."

Other Laboratory Findings. With extremely rare exceptions, there is, in cases of pernicious anemia,

FIGS 235-2. Variations in mean volume of red corpuscles compared with reticulocyte count in three cases of pernicious anemia. The mean corpuscular volume (CV) and the red cell count (RBC) are represented as percentages of their respective average normal values. By this method the red cell count and mean corpuscular volume of a hypothetical normal individual would fall on the line at 100 per cent. Reticulocytes are recorded directly. The abscissa records number of days following the commencement of liver therapy. (Wintrobe: *Relation of Variations in Mean Corpuscular Volume to Number of Reticulocytes in Pernicious Anemia*, *J. Clin. Invest.*, 13:609, 1934.)

persistent failure to secrete hydrochloric acid in the stomach even following the injection of histamine. Furthermore, in the great majority of cases, the enzymes are deficient as well, and only a small amount of mucus rewards the gastric extraction.

In addition to the bilirubinemia, already mentioned, the urobilinogen content of the urine and stools is increased. Detailed examinations reveal many other evidences of metabolic disturbance involving, especially, protein and uric acid as well as fat metabolism.

Diagnosis. When the combination of the classic symptoms—weakness, sore tongue, and numbness and tingling—together with macrocytic anemia and achlorhydria is found, there need be no difficulty in diagnosis. Confusion may arise if the symptoms have led one to suspect some other condition and the blood examination has not been appropriate to demonstrate the existence of a macrocytic anemia. Confusion may also arise when symptoms referable to the nervous system are prominent and anemia is only moderate or slight in degree. For all practical purposes, since achlorhydria is so characteristic a feature of pernicious anemia, a diagnosis of pernicious anemia should never be made without demonstrating a failure to secrete hydrochloric acid following the injection of histamine. The existence of a macrocytic anemia, as indicated by calculation of red corpuscle size, should, furthermore, be confirmed by examination of the blood smear. In practically all cases such anemia is found to be associated with evidences of altered pigment metabolism

such as some increase in plasma bilirubin and an increased output of urobilinogen in the urine and stools. Where anemia is slight in degree, the combination of achlorhydria, slight macrocytosis as indicated by calculation of mean corpuscular volume and by the presence of macrocytes in the blood smear, together with a slight degree of bilirubinemia, makes pernicious anemia highly likely.

It must be kept in mind that the demonstration of macrocytic anemia is not in itself diagnostic of pernicious anemia, for, as already indicated, macrocytic anemia may appear under a variety of circumstances. When the macrocytic anemia is part of another disorder such as "aplastic" anemia, "aleukemic" leukemia, or some type of hemolytic anemia, differentiation is important, for vitamin B₁₂ or folic acid therapy is then valueless. In aplastic anemia, achlorhydria is only sometimes present, glossitis is rare, and signs of involvement of the nervous system, such as loss of vibratory sense, are unusual. In aleukemic leukemia, sternal marrow examination should reveal a characteristic picture quite different from that of pernicious anemia, and in hemolytic anemia the marrow is normoblastic, not megaloblastic. Even when the macrocytic anemia is accompanied by megaloblastic bone marrow, differentiation is important, since some forms, unlike pernicious anemia, are not permanent in character and do not require treatment for the remainder of the patient's life. Certain rare megaloblastic macrocytic anemias, furthermore, do not respond to the administration of vitamin B₁₂. Some of these conditions are described briefly below.

It is important that diagnosis be established accurately before treatment is initiated, since, as already indicated, a diagnosis of pernicious anemia implies the need for therapy for the rest of the patient's life. In doubtful cases, a therapeutic test, if properly performed, can be very helpful. It is important, however, that the test be made with vitamin B₁₂ alone and not with some agent containing iron or other substances in addition, and that the reticulocyte response be observed daily for 7 to 10 days until a positive or negative result has been obtained.

The discovery of vitamin B₁₂ and the fact that the cobalt contained therein can be labeled radioactively have provided a method whereby the absorption of this vitamin can be measured. This offers a means by which defective absorption of the vitamin from the gastrointestinal tract can be demonstrated even in the absence of anemia, as in treated cases of pernicious anemia, and to some extent megaloblastic macrocytic anemias other than pernicious anemia can be differentiated from that condition. Several different techniques are available, but the most commonly used one, the *Schilling test*, depends on measurement of the excretion of the

administered radioactive material in the urine. When radioactive vitamin B₁₂ is given by mouth to persons who can absorb it, radioactivity will appear in the urine if the person is "flooded" with an intramuscular injection of nonradioactive vitamin B₁₂. Normal individuals have been found to excrete 11 to 26 per cent of the orally administered radioactivity in the urine in the next 24 hr, depending on the size of the dose (0.5 to 2.0 μ g). Patients with pernicious anemia have been observed to excrete only 0 to 7.0 per cent under these conditions. In them the simultaneous administration of intrinsic factor and radioactive vitamin results in increased excretion (3.1 to 30, average 9.8 per cent).

Prognosis. With appropriate therapy it is now possible to restore the blood to normal and to promote a return of the general nutrition to normal. If changes are present in the nervous system, their advance can at least be halted, and in some cases improvement may take place. The danger in pernicious anemia arises from failure to continue therapy and from complications and intercurrent conditions. In a chronic ailment like pernicious anemia, other diseases develop in the course of time. Among these, carcinoma of the stomach is particularly noteworthy, since the incidence of this disease in patients with pernicious anemia is more than three times as great as in other individuals. When changes in the nervous system exist, particularly if they involve the urinary sphincter, infection may occur. The existence of infection at the time of relapse may seriously interfere with the response to therapy.

Treatment. Treatment, in so far as the blood changes are concerned, is extremely simple. The administration of an adequate amount of vitamin B₁₂ is followed by a reticulocyte response which reaches its maximum 5 to 7 or 8 days following initiation of therapy. This is succeeded, as the reticulocyte count falls to normal, by a rapid disappearance of anemia and by the production of cells of normal size and shape. The leukocyte and the platelet counts likewise return to normal, bilirubinemia disappears, and the increased quantities of urobilinogen in the urine and stools are reduced to the normal range. The gastric achlorhydria persists.

Effective treatment may produce subjective improvement within 48 hr, and evidence of a change is often noted by the patient before the reticulocytes increase. There is a gain in appetite and a sense of well-being. Tongue symptoms, if present, disappear promptly. On the other hand, neural symptoms do not change quickly. Although in the course of 2 months from the beginning of treatment the patient usually attains a normal blood, the neurologic symptoms may still be present. However, those of milder intensity are likely to decrease or disappear.

The most efficient means of treatment is by the

intramuscular injection of vitamin B₁₂. The effects of the administration of vitamin B₁₂ in pernicious anemia appear to be in every way similar to those produced by liver extract and, like the latter, are very much more pronounced when the vitamin is given parenterally than when it is taken orally (60 to 100 times). The minimal effective intramuscular dose of vitamin B₁₂ is 1 μ g, and good hematopoietic responses may be expected from doses of 10 μ g daily. Larger amounts up to 80 μ g or more daily produce greater effects, the mean response being roughly proportional to the logarithm of the dose. As larger doses are given, however, a greater proportion is promptly excreted.

For a patient in relapse, between 1,000 and 5,000 μ g vitamin B₁₂ is given, since the substance is needed not only to produce a remission but to replenish the greatly depleted body stores. However, this is best administered in divided doses in the course of the first 2 weeks or more of therapy; otherwise, much of the vitamin will be excreted before it can be used or stored, as already indicated. An injection of 100 μ g is a satisfactory amount to be given at one time. If possible, reticulocytes should be counted daily in order that the effectiveness of therapy, or lack of response, may be demonstrated early. An increased quantity of red cells as measured by the volume of packed red cells is not usually detectable before 10 days.

Maintenance therapy may be calculated on the basis of approximately 2 μ g vitamin B₁₂ for each day, but this does not need to be given at intervals shorter than a month or two; i.e., 60 μ g is injected intramuscularly every 30 days or 120 μ g every 60 days.

Intravenous therapy is unnecessary. Oral therapy with liver extract or B₁₂-intrinsic factor combinations is inconvenient, since daily intake is necessary. Only where some idiosyncrasy on the part of the patient exists, or where sensitivity to the parenteral administration of vitamin B₁₂ cannot be overcome otherwise, is oral therapy justified. Then 1,000 μ g vitamin B₁₂ orally each day is preferable to the use of vitamin B₁₂-intrinsic factor combinations or liver extracts. Folic acid should not be used.

The diet should be such as to restore the patient to a state of normal nutrition and to maintain him so, but need not contain any unusual foods, except perhaps where neurologic changes are present. In such cases, it may be wise to recommend the consumption of, say, a half pound or more of cooked liver per week. This recommendation is made since information is still lacking as to the exact nature of the deficiency which leads to the development of changes in the nervous system. By the consumption of whole liver the patient possibly obtains substances of value in addition to the antianemic factor.

Transfusion is rarely, if ever, required in pernicious anemia, since a physiologic response can be achieved in 48 to 72 hr if vitamin B₁₂ is given parenterally. Since the patient's anemia has developed gradually, he has become adjusted to it. Where the cardiovascular system is imperfect, transfusion, by producing a sudden increase in blood volume, may sometimes be harmful and may precipitate acute cardiac failure with pulmonary edema. Iron is not needed as an adjunct except where iron deficiency exists as well. Supplementary therapy with various vitamins is likewise unnecessary. These can be and should be furnished in the diet in the form of food. The administration of dilute hydrochloric acid (USP), in amounts of 4 to 8 ml t.i.d. with meals, is sometimes of value when gastrointestinal complaints persist, particularly eructations or frequent bowel movements. In the absence of such complaints hydrochloric acid is unnecessary.

Particularly where changes in the nervous system exist, confinement to bed should be as brief as possible, and the patient should be encouraged to use the limbs even when lying in bed. In addition, passive movement, massage, and dry heat are valuable for improving the tone of the muscles. Physiotherapy may permit adjustment to permanent damage resulting from the neurologic changes.

The development of an intercurrent disease, particularly infection, calls for an increase in the amount of vitamin B₁₂ therapy, since requirements under such conditions seem to be increased.

Vitamin B₁₂ therapy has now replaced treatment with liver extract. Even when "refined" liver extracts were used, sensitivity was sometimes observed to develop in the form of severe flushing, dizziness, a sense of oppression, or urticaria following its intramuscular administration. Sometimes even peripheral vascular collapse occurred. Sensitivity to the crystalline vitamin B₁₂ is extremely rare.

Megaloblastic Macrocytic Anemias Other than Pernicious Anemia (Table 235-1)

Nutritional Macrocytic Anemia. This term refers to macrocytic anemia arising from dietary deficiency, as distinguished from deficiency resulting from lack of intrinsic factor or from faulty absorption. Since such anemia has been seen most often in the tropics, *tropical macrocytic anemia* is another synonym. The condition is particularly common in pregnant women. Weakness, shortness of breath, sore mouth, sore tongue, diarrhea, and edema are common complaints. In contrast to pernicious anemia, in nutritional macrocytic anemia achlorhydria is no more common than in the population in general, and degenerative changes in the nervous system are practically never found. The blood picture

and bone marrow are indistinguishable from those of pernicious anemia. Tropical macrocytic anemia probably is not a single clinical entity. In many cases the anemia has been relieved by the administration of yeast, Marmite (autolyzed yeast), or liver. In some cases a good hematopoietic response has followed the administration of pteroylglutamic acid, and in a few, a good response to vitamin B₁₂ and even to oral penicillin has been reported. In certain cases, however, these agents have not been effective, and the need for still another factor (Wills's factor) has been postulated. That some form of dietary deficiency is the cause of this disorder is indicated by the observation that it does not recur if the diet is satisfactory.

Nutritional macrocytic anemia is uncommon in the Temperate Zones. Few of the instances of macrocytic anemia seen in *pellagra* can be accounted for by a lack of extrinsic factor in the diet. In other cases faulty absorption is important, and in many both mechanisms play a role. In *sprue* and in *idiopathic steatorrhea*, as described elsewhere (p. 557), inadequate absorption is the main cause for the development of macrocytic anemia. In Great Britain in particular, occult idiopathic steatorrhea with insignificant alimentary symptoms but accompanied by megaloblastic macrocytic anemia is not uncommon. This usually responds much better to the administration of pteroylglutamic acid than to vitamin B₁₂.

Patients described at one time as having "achrestic anemia" and "refractory megaloblastic anemia," because they failed to respond to liver therapy, may have impaired metabolism of folic acid or complex deficiencies of folic acid, ascorbic acid, choline, or perhaps other substances essential for the metabolic steps which result in normal erythropoiesis.

In Pregnancy. In addition to megaloblastic anemia in pregnancy which may be regarded as nutritional macrocytic anemia, as mentioned above, such anemia is sometimes seen in the absence of dietary deficiency. Although this type of anemia is often refractory to liver extract or vitamin B₁₂, most patients have responded to folic acid; the prognosis, which was very poor at one time, has thus been improved. The pathogenesis of this form of megaloblastic anemia is obscure. Increased demands as the result of the needs of the fetus, defective utilization, or some other metabolic abnormality are possibilities which have not been excluded.

Following Surgery. Following *total gastrectomy*, megaloblastic anemia may develop because the source of intrinsic factor has been removed. The absorption of orally administered vitamin B₁₂ has been shown to be impaired. Following *partial gastrectomy* the incidence of megaloblastic anemia is very much lower than after total gastrectomy, although iron-deficiency anemia is relatively common.

The macrocytic anemia seen in association with intestinal strictures and anastomoses has been attributed to impaired absorption, but as good hematoietic responses have been observed when tetracyclines were given, it seems plausible that the anemia is caused by the colonization of the small intestine by abnormal bacteria which in some way divert folic acid or vitamin B₁₂ from the host.

In Liver Disease. Macrocytic anemia occurs in a variable number of cases of chronic liver disease and it is megaloblastic in a few. No wholly satisfactory explanation for the latter has been found. It is conceivable that the requirements for folic acid and vitamin B₁₂ may be increased or their storage or utilization impaired, or that other factors are involved.

In Hypothyroidism. Macrocytic anemia is sometimes seen in hypothyroidism, but the bone marrow is usually hypoplastic and normoblastic, and desiccated thyroid, not liver extract, vitamin B₁₂, or pteroylglutamic acid, is effective in relieving the anemia. Defective intestinal absorption of vitamin B₁₂, uninfluenced by intrinsic factor, has been demonstrated in some cases.

In Fish Tapeworm Infestation. True megaloblastic macrocytic anemia is seen, in Finland especially, in persons harboring the tapeworm, *Diphyllobothrium latum*. The anemia is attributable to competition with the host by the worm for vitamin B₁₂. How this interference is accomplished is unclear; perhaps by utilization of the vitamin, breakdown of its interaction with intrinsic factor, or prevention of its absorption through the intestinal wall.

During Administration of Antimetabolites. One of the toxic effects of amethopterin and 6-mercaptopurine, used in the treatment of leukemia, is the production of megaloblastic anemia. Interference with the metabolism of folic acid appears to be the explanation for the development of such anemia in a small proportion of patients receiving anticonvulsant drugs, such as diphenylhydantoin sodium, primidone, and barbitol derivatives, although the possible coexistence in the individuals affected of some degree of folic acid deficiency must be considered to be likely.

In Cases of Excessive Demands. In rare instances of very active hematopoiesis, especially in hemolytic anemias, megaloblastic anemia has been observed, presumably because the demands for building materials exceeded those available in persons whose stores of these substances were marginal.

Review of the conditions in which megaloblastic anemia may be encountered thus reveals that under certain circumstances dietary deficiency of folic acid may develop and result in nutritional macrocytic anemia. In other patients there may be defective absorption of folic acid (sprue, idiopathic steatorrhea), but in some such patients the absorption of vitamin B₁₂ may be impaired as well. In still other cases, alterations in the gastrointestinal tract may lead to consumption or destruction of one or both of these substances, or an antimetabolite may be produced there (fish tapeworm anemia, intestinal strictures and anastomoses). Only following total gastrectomy is absorption of vitamin B₁₂ impaired in a manner corresponding to that encountered in pernicious anemia; i.e., as the result of lack of intrinsic factor. Various combinations of defects in dietary content, absorption, consumption, destruction, or antagonism may result in various degrees of deficiency of vitamin B₁₂ or folic acid or both. In addition, it has been postulated that vitamin B₁₂ in some manner influences the storage, absorption, and utilization of folic acid and that when vitamin B₁₂ is lacking, these functions are impaired.

HEMOLYTIC ANEMIAS

Manifestations. Under the heading of hemolytic anemias a number of conditions may be included which differ widely in etiology, symptomatology, severity, and course. The symptoms depend upon the rapidity and extent of hemolysis, its duration, and whether or not it is taking place in the blood stream or in the reticuloendothelial system. Jaundice is a sign common to all, but its degree may be such as to be barely perceptible (when it is often overlooked) or so great as to be very striking. Other symptoms may be entirely absent. Thus patients with hereditary spherocytosis are "more yellow than sick" except when a hemolytic crisis occurs. In other cases there may be slowly progressive anemia and gradually increasing jaundice. The anemia may become profound and yet there may be few manifestations, since in such cases there is time for cardiovascular adjustments (p. 208) to be made. In chronic hemolytic anemia, splenomegaly is common and the liver may be enlarged. Complications such as gallbladder disease or chronic leg ulcers may develop.

HEMOLYTIC ANEMIAS

On the other hand, the onset of hemolytic anemia may be heralded by a severe, shaking chill followed by high fever, malaise, headache, and pain in the back, abdomen, or limbs. The abdominal pain may be so severe and may be accompanied by such marked muscular rigidity and spasm as to simulate an acute surgical condition. If the hemolysis is rapid and severe enough, profound prostration and shock, accompanied by anuria and oliguria, may ensue. When urine is passed, it is found to be very dark. Jaundice develops rapidly. As anemia ensues, weakness, palpitation, dyspnea, tachycardia, cyanosis, cardiac enlargement, hemic murmurs, vertigo, faintness, and other manifestations of rapidly developing anemia (Chap. 23) make their appear-

ance. In certain types of acute hemolytic reactions, urticaria, vascular disturbances suggesting Raynaud's phenomenon, and thrombosis and gangrene may develop.

All grades, from such acute fulminating disorders of several days' duration to extremely benign conditions of many years' standing, may be encountered. A chronic, congenital process may be interrupted by acute exacerbations.

Hematologic Manifestations. The hematologic manifestations which accompany acute blood destruction consist of an initial phase of rapid destruction of red corpuscles and a second phase of rapid blood regeneration. These two phases usually overlap, especially when the hemolytic agent acts over a prolonged period of time.

The anemia may be mild or severe, depending upon the intensity and duration of the hemolytic process. It is usually normocytic but may be macrocytic, especially during the stage of rapid regeneration when many relatively immature and reticulated cells are present. It is not uncommon to find 10 to 25 per cent reticulocytes in chronic cases, and as many as 60 per cent or even more in acute cases. Polychromatophilia, nucleated red blood corpuscles, and Howell-Jolly bodies are usually present. There generally is marked variation in the size of the cells (anisocytosis) and usually little variation in their shape (poikilocytosis), except in patients with sickle-cell anemia. Spherocytes may be numerous.

Marked stimulation of the leukopoietic tissues, manifested by leukocytosis and a "shift to the left," with myelocytes and even rare myeloblasts, accompanies the red corpuscle regeneration. Platelets may increase in number, and large, bizarre forms may make their appearance. In certain cases, however, and especially in paroxysmal nocturnal hemoglobinuria, leukopenia and thrombocytopenia may be present.

The bone marrow is hyperplastic. There is a great increase in normoblasts and a consequent reduction in the myeloid leukocyte/erythrocyte ratio from the normal of 4 or 5:1 to about 1:1 or even less. The normoblasts are chiefly polychromatophilic and orthochromatic forms, as a rule there are not many pronormoblasts or basophilic normoblasts. Megaloblasts, so characteristic of pernicious anemia and related macrocytic anemias, are not present.

Pigment Metabolism. When the degree and rate of blood destruction are very great, hemoglobin is liberated into the plasma and, if the hemoglobin-binding capacity of the plasma (haptoglobin, p. 203) is exceeded, free hemoglobin is excreted by the kidneys and hemoglobinuria results. However, the finding of red urine must not be assumed to be necessarily indicative of hemoglobinuria. The color may also be produced by intact red corpuscles,

porphyrin, or myoglobin. Microscopic and spectroscopic examination of the urine will reveal the cause of the abnormal color. Under certain circumstances hematin (p. 204) may be released.

More often, blood destruction is less rapid. In such cases hemoglobinemia and hemoglobinuria are not found and there is only an increase in the icterus index, serum bilirubin, and urobilinogen excretion in the urine and feces. The stools assume a dark color, and from 300 to 4,000 mg urobilinogen may be found in a 24-hr stool, as compared with the normal of 40 to 250 mg. The 24-hr urine may contain 5 to 200 mg urobilinogen (normal, 0 to 35 mg). The fecal urobilinogen may be increased when the urine urobilinogen and the bilirubin in the blood are not significantly greater than normal.

The quantity of bilirubin in the plasma may rise as high as 10 mg per 100 ml. The reaction is indirect but some increase in direct or "one-minute" bilirubin (bilirubin glucuronide) may also occur. The intensity of the bilirubinemia depends not only on the extent of the blood destruction but also on the capacity of the liver to remove the pigment from the blood stream and excrete it in the bile. A normally functioning liver is capable of excreting large quantities of bilirubin, but it is assumed that as anemia and consequent hypoxemia develop, its functional capacity becomes impaired and bilirubin accumulates in the blood stream.

Classification

The hemolytic disorders may be classified in various ways, none of which is entirely satisfactory. A clinical classification based on the severity of the manifestations may be confusing, since a chronic process may come to notice only during an acute exacerbation. Differentiation of congenital and acquired forms is useful. Better still, however, is classification on the basis of pathogenesis, even though understanding of the pathogenesis of the hemolytic anemias is still incomplete.

By transfusing corpuscles which differ from those of the recipient with respect to their MN or Rh type or by giving group O corpuscles to recipients belonging to one of the other three major blood groups, it has been shown that when normal corpuscles are transfused to patients in whom there is an extracorporeal cause for hemolysis, the donated corpuscles are destroyed as rapidly as the patient's own corpuscles. If, on the other hand, the patient's corpuscles are removed from their abnormal environment and transfused to a normal recipient, their survival time is normal. Hemolytic anemias which have been shown to be or are thought to be of this type are listed in group I of Table 235-2. Group II includes disorders in which hemolysis is the result of a defect in the patient's own

Table 235-2. CLASSIFICATION OF HEMOLYTIC DISORDERS

I. Extracorporeal causes

A. Acute hemolytic anemias due to immune body reaction

1. Isoagglutinins anti-A, anti-B (transfusion reactions)
2. Isoagglutinins anti-Rh, Kell, Duffy, etc. (hemolytic disease of the newborn, "intra-group" transfusion reactions)
3. Cold hemolysins (paroxysmal cold hemoglobinuria)

B. Idiopathic acquired hemolytic anemias

C. Secondary, or symptomatic, hemolytic anemias

1. Hodgkin's disease
2. Chronic lymphocytic leukemia, lymphosarcoma
3. Disseminated lupus erythematosus
4. Metastatic carcinomatosis
5. Sarcoidosis, myelofibrosis
6. Liver disease, ovarian tumors
7. Thrombotic thrombocytopenic purpura

D. Infectious agents

1. Malaria
2. Bartonella (Oroya fever)
3. Septicemia: *Clostridium welchii*, *Vibrio comma* (cholera), rarely others
4. Viruses (atypical pneumonia, infectious mononucleosis)

E. Chemical agents

1. Related to size of dose

a. Phenylhydrazine	f. Phenacetin
b. Toluene	g. Aniline
c. Trinitrotoluene	h. Methyl chloride
d. Benzene	i. Arsine
e. Acetanilid	j. Lead
2. Depending on hypersensitivity

a. Sulfonamides	h. Para-phenylenediamine
b. Quinine, quinidine	i. Naphthalene
c. Pamaquine	j. Sulfones
d. Primaquine	k. Nitrofurantoin
e. Para-aminosalicylic acid	l. Phenothiazine
f. Benzadrine	m. Vitamin K substitutes
g. Mesantoin	

F. Physical agents (heat—severe thermal burns)

G. Vegetable and animal poisons

1. Vegetable poisons
 - a. Fava bean (*Vicia faba*)
 - b. Castor bean (ricin)
2. Animal poisons
 - a. Snake venoms

II. Intracorporeal defects

A. Hereditary spherocytosis (familial or congenital hemolytic jaundice)

B. Hereditary elliptocytosis

C. Hereditary nonspherocytic hemolytic anemias

D. Hereditary leptocytosis (thalassemia, Mediterranean anemia)

E. Sickle-cell disease

F. Other hereditary hemoglobinopathies (C, E)

Table 235-2. CLASSIFICATION OF HEMOLYTIC DISORDERS (continued)

G. Combinations of thalassemia and sickle-cell disease or other hemoglobinopathies

H. Paroxysmal nocturnal hemoglobinuria

I. Miscellaneous congenital hemolytic anemias ("inclusion body," "Heinz body," "Pappenheimer body")

red corpuscles. The patient's corpuscles, when given to a normal recipient, can be shown to be disposed of more rapidly than those of the recipient, while the latter's corpuscles, if transfused into the patient, maintain a normal "life span." It may be noted that, in the main, hemolytic anemias due to intracorporeal defects are familial and hereditary; those produced by extracorporeal factors are "acquired."

Acute Hemolytic Anemias Due to Immune Body Reactions. The naturally occurring agglutinins α and β cause hemolysis when incompatible blood is given by transfusion. When hemolytic transfusion reactions take place in spite of A, B, and O blood-group compatibility, they are attributable in most instances to the development of anti-Rh (D) agglutinins. Next in frequency are the Kell antigen and antibody. Other blood groups are only rarely involved (p. 440). Such agglutinins are also responsible for the development of hemolytic disease of the newborn (*erythroblastosis fetalis*), a condition in which the red corpuscles of an Rh-positive fetus are destroyed as the result of the action of antibodies produced in the Rh-negative woman carrying the fetus.

Although the number of possible causes of hemolytic anemia is large, as Table 235-2 indicates, in a very significant number of cases of acquired hemolytic anemia no cause is found and no associated disease is recognized. *Idiopathic cases* have been observed at all ages, from five months to seventy-eight years, but females are more often affected than males. The clinical manifestations range in the extreme. The course may be acute, severe, and fulminating, or the illness may be insidious in onset and chronic in course. In the latter instances, repeated attacks of greatly exaggerated blood destruction may punctuate the course and may be followed by spontaneous remissions. By and large the manifestations are rarely as mild as they may be in hereditary spherocytosis. The hematologic features are similar to those of other hemolytic anemias, varying according to the severity of the condition. In most instances, however, certain immunologic manifestations may be demonstrated if they are looked for. The introduction of serologic methods like the Coombs test has made possible the demonstration of antibodies in the majority of cases of idiopathic acquired hemolytic anemia.

There appear to be several varieties of idiopathic acquired hemolytic anemia. They are, in part, associated with differences in the type of antibody which is found. In the majority a "warm" antibody is present; i.e., the antibody reacts well at 37°C and is not potentiated at lower temperatures. The most common warm antibodies are "incomplete"; that is, they sensitize normal erythrocytes to anti-globulin serum but do not cause agglutination in a saline medium. The sensitization is not inhibited by previous heat inactivation of the patient's serum at 56°C and it is increased only slightly by acidification of the serum to pH 6.5 or 7. Typically, these warm antibodies cause agglutination and not hemolysis. The sensitizing antibodies usually are γ -globulins.

"Cold" antibodies are markedly potentiated by reducing the temperature below 37°C. These antibodies are "incomplete," but they may also act as "complete" agglutinating antibodies and under certain circumstances may also bring about hemolysis. Two main forms of cold antibodies have been demonstrated in acquired hemolytic anemias. The common, typical type is a powerful antigen; the rare variety is similar to the Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria. In cases of acquired hemolytic anemia associated with the presence of cold antibodies, cyanosis and Raynaud's phenomenon on exposure to cold as well as hemoglobinuria may be noted. Spherocytes are not conspicuous and osmotic fragility may be normal. The course of these cases is generally chronic and often is relatively mild. They most commonly occur in elderly persons.

In addition to these warm and cold autoantibodies, it is not uncommon to find other manifestations of abnormal protein formation in patients with acquired hemolytic anemia. Thus, antibodies against lipid antigens may be present and may give rise to false positive Wassermann and Kahn reactions. This is especially frequent in disseminated lupus erythematosus. Again, serum complement may be reduced and hypergammaglobulinemia and cryoglobulins may develop.

It was assumed at first that the autoantibodies found in acquired hemolytic anemia were nonspecific; i.e., that they reacted with all types of human red cells without relation to any known blood group antigens. In some cases, however, the autoantibodies have been found to be specific and were directed against various Rh antigens and, more rarely, against other blood groups, such as Kell, B, and O. The serology of the acquired hemolytic anemias is complicated, however. Autoantibodies without apparent specificity have been observed in the same blood as those in which specific antibodies were discovered. Furthermore, it has been observed that the antibodies of one patient often

differ considerably from those of another in temperature requirements, specificity, chemical nature, and in their reactions *in vitro*. A few cases have been described in which the patients' serums contained a potent agglutinin for enzyme-treated cells, but this was not associated with a positive direct Coombs test. In cases in which cold antibodies have been demonstrated, there has not been a clear correlation between their titer and hemolysis, nor has there been such exposure to cold as might be expected to lead to agglutination and subsequent mechanical destruction of the red corpuscles.

Certain features serve to distinguish chronic hemolytic anemia with erythrocyte-bound antibody from other types of hemolytic anemia. As already indicated, warm or cold hemagglutinins are present and the Coombs test (p. 1293) is positive. Spherocytosis is usually marked when the disease is active, and at such times the osmotic fragility of the red corpuscles is irregularly increased and their mechanical fragility is also increased. Even normal transfused cells become spherical, their fragility becomes increased, and they are rapidly destroyed. In quiescent stages, however, the spherocytosis may be absent, and osmotic and mechanical fragility may be normal.

It has been pointed out that oxalated blood from patients with hemolytic anemia associated with immune bodies may have a granular appearance when examined with a hand lens as the blood is allowed to flow in a thin layer along the side of a glass container. In rare cases this may even be seen with the naked eye. The phenomenon is attributable to the agglutination of the red corpuscles in the plasma.

Other Hemolytic Anemias, Presumably Due to Extracorpuscular Causes. The clinical manifestations of the hemolytic anemias associated with various disorders ("symptomatic" hemolytic anemias) are similar to those in cases of the idiopathic variety except for the presence of manifestations of the underlying disease. The latter, however, are sometimes not apparent and must be sought out carefully. Although it was at first thought that erythrocyte-bound antibodies do not develop in cases of symptomatic hemolytic anemia, with the introduction of appropriate serologic techniques it is becoming clear that at least a great proportion of these cases are of the immune body type.

Table 235-2 lists the large variety of infectious, chemical, and physical agents which may be associated with the development of hemolytic anemia. Hemolytic anemia associated with exposure to chemical agents can develop in a number of different ways. Some chemical agents cause anemia which is related in its severity to the quantity of the chemical absorbed. Other chemicals, such as benzene and trinitrotoluene, may have an earlier

hemolytic effect which is followed by a toxic, inhibitory action on the bone marrow, with aplastic anemia as the ultimate result. Another group are the derivatives of aniline and the nitro compounds, which more regularly cause methemoglobinemia but may also cause blood destruction. Plumbism represents still another category.

In addition to these, there are chemical agents which cause hemolytic anemia only in a small proportion of exposed individuals. Even a small dose may precipitate the reaction. Because the nature of one form of such drug sensitivity was first disclosed in the course of a study of sensitivity to the antimalarial compound primaquine, it has come to be designated as the *primaquine-sensitive type of hemolytic anemia*. It has been shown that in such sensitive persons the glucose 6-phosphate dehydrogenase (G6PD) activity of the red blood corpuscles is substantially reduced below the normal. This enzyme is concerned with the regeneration of reduced triphosphopyridine nucleotide (TPNH), which, in turn, is required in the reduction of oxidized glutathione. It was observed that the reduced glutathione (GSH) level of sensitive erythrocytes was consistently lower than that of nonsensitive cells and that a rapid fall in red cell GSH occurred when primaquine was administered to sensitive individuals. This phenomenon can also be demonstrated *in vitro* by incubating sensitive cells with acetyl phenylhydrazine. Various tests have been devised whereby "primaquine sensitivity" can be demonstrated. Hemolytic anemia associated with a large number of drugs, some of which are listed in Table 235-2, is of this type. It is not known whether the fundamental abnormality in erythrocyte metabolism is GSH depletion or whether this is only a convenient indicator of other important changes. It has been shown that the abnormality is an inherited trait which appears to be transmitted as a sex-linked, incompletely dominant gene of intermediate penetrance. Males are affected, but in the heterozygous female the defect may range from full expression to nonpenetrance. The abnormality is present in about 7 per cent of American Negroes and in Caucasians of Italian and Greek extraction as well as in other Mediterranean peoples. The hemolytic anemia associated with exposure to the fava bean may depend on the same mechanism or a similar one. An important distinction between the red cell abnormality in these sensitive persons and that seen in disorders classified in Table 235-2 under the general heading of Intracorporeal Defects, such as hereditary spherocytosis, is that the red cell abnormality of sensitive persons has no known deleterious effect on the individual or on the red cell life span in the absence of the offending chemical agent.

Hemolytic reactions to all drugs cannot be ex-

plained by the heritable enzymatic mechanism described above. However, nothing is known concerning the pathogenesis of other forms of drug idiosyncrasy.

Intracorporeal Defects. A number of the disorders coming under this head are described separately below.

Mechanisms of Hemolysis. Various processes condition or cause the destruction of red corpuscles: phagocytosis, agglutinins and hemolysins, osmotic lysis, mechanical factors, and sequestration with erythrostatics. The importance of phagocytosis is not clear. Some regard it as a primary and important factor, while others relegate it to an accessory role dependent on other mechanisms of red corpuscle destruction. Various types of hemagglutinins and hemolysins have been described, as already mentioned. Immune hemolysins are not found free in the serum except in disorders which require special conditions for their maximum operation. Thus in paroxysmal cold hemoglobinuria a fall in temperature is required for maximum activity of the hemolytic system, while in paroxysmal nocturnal hemoglobinuria a fall in the pH of the blood is necessary. In most instances immune hemagglutinins remain attached to the red corpuscle. The Coombs or "developing" test serves to demonstrate such factors (p. 1293).

The role of mechanical factors is indicated by the fact that the osmotic and mechanical fragilities of the red corpuscles increase when the corpuscles are placed in natural or artificial immune serums in which hemolysins and agglutinins are present. Similar changes in fragility have been observed in association with the action of hemolytic agents, such as saponin, or physical factors, such as heat. Osmotic lysis, usually determined by the familiar hypotonic saline fragility test, probably does not operate *in vivo* except perhaps in the spleen under certain conditions. It is a plausible hypothesis that mechanical trauma is the ultimate mechanism whereby cell destruction occurs under normal circumstances and in many varieties of hemolytic anemia. It has been shown that nearly spherical cells, strongly agglutinated cells, and those with weakened cell membranes are abnormally susceptible to mechanical destruction. In certain cases of acquired hemolytic anemia, increased mechanical fragility has been observed when osmotic fragility was normal. It was found that such cells did not survive normally in the circulation of normal individuals. The increased mechanical fragility of sickled masses of erythrocytes may explain the increased red corpuscle destruction in sickle-cell anemia.

The term *erythrostatics* has been applied to the processes to which red corpuscles are subjected when denied free access to fresh plasma. The spleen appears to have the property of selectively remov-

ing and concentrating spheroidal cells. Erythrocytosis may lead to increased osmotic and mechanical fragility of the red corpuscles and thereby favor their destruction. It has been suggested that the spleen is of importance in hereditary spherocytosis because of the inherently abnormal susceptibility of the red corpuscles to the effects of erythrocytosis. It was demonstrated that in a patient with this disease who had received transfusions of identifiable normal corpuscles, the spleen, removed at operation, had selectively retained the patient's own corpuscles. Perfusion experiments have shown that even the spleen from a case of purpura hemorrhagica, where no hemolytic process existed, likewise selectively removed transfused red corpuscles from cases of hereditary spherocytosis but did not retain normal corpuscles.

Sequestration in the spleen and also in the liver plays an important role in acquired hemolytic anemias. In sequestering sensitized red corpuscles from the circulation the spleen behaves as a highly proficient, passive filter. Thus, it has been shown that when sensitized red corpuscles are injected in the circulation of normal subjects, they are agglutinated by the plasma globulins, following which they are sequestered in the spleen and are hemolyzed within a few minutes. The speed of the hemolysis is such as to suggest the presence of a preformed lysis; leukocytes may be involved in this lytic process. However, in contrast to the fate of these sensitized corpuscles coated with "incomplete" antibodies, in reactions involving "complete" antibodies, as when red corpuscles are injected into normal subjects hyperimmunized against them, sequestration and destruction occur in the liver to a greater extent than in the spleen.

Studies of spontaneous hemolysis of red corpuscles *in vitro* (autohemolysis) have led to the recognition of a metabolic defect in the red corpuscles of hereditary spherocytosis. The continued presence of glucose during incubation of the red corpuscles was observed to retard markedly the potassium loss and the increase in osmotic fragility of the cells. It was possible to demonstrate that abnormalities in the dynamics of intracellular carbohydrate metabolism exist. Thus, using radioactive phosphorus as a tracer, it was found that in cells from patients with hereditary spherocytosis there is a smaller flux of P^{32} into adenosinetriphosphate and 2,3-diphosphoglyceric acid than in normal cells and a concurrent increase in the flux into orthophosphate. It was shown also that in many instances the metabolic lesion could be reversed with adenosine and glucose. Thus, some of the deleterious effects of erythrocytosis can be explained. An adequate rate of supply of energy-rich phosphate bonds is necessary for the maintenance of the biconcave shape of the red corpuscle. Energy production may be defective as

the result of genetically controlled enzyme deficiencies or functional inadequacies. Such red corpuscles are less well able to maintain their integrity than normal ones.

Study of a Patient with a Hemolytic Disorder

Hemolytic anemia can be recognized by the development of certain symptoms and signs, certain changes in the blood and bone marrow, and characteristic alterations in pigment metabolism, as already outlined. The differentiation of the various hemolytic disorders is important since treatment depends on their nature. The history alone may suffice to reveal an etiologic agent or may indicate that one is dealing with one of the familial or hereditary disorders. Physical examination may reveal one of the conditions of which hemolytic anemia can be symptomatic. In addition, certain simple tests have been devised which give some clue to the nature of the disorder.

Osmotic Fragility Test. In certain cases of hemolytic anemia one demonstrates, by this test, the susceptibility of red corpuscles to hemolysis in concentrations of salt which fail to cause rupture of normal corpuscles. Such osmotic fragility is characteristic of corpuscles which are more nearly spherical than normal corpuscles. The test is generally positive in hereditary spherocytosis and negative in acquired forms. Unfortunately, however, there are exceptions to this statement. Spherocytosis and increased osmotic fragility are encountered in certain acquired cases, especially in an acute phase. The sensitivity of the test can be increased by first incubating the corpuscles to be tested *in vitro* at body temperature for 24 hr. Under such conditions the fragility of normal corpuscles is increased slightly; that of corpuscles from cases of hereditary spherocytosis is increased markedly and symmetrically.

Mechanical Fragility Test. A small amount of ovalated or defibrinated blood is placed in an Erlenmeyer flask containing glass beads and rotated, following which the hemoglobin liberated from the cells is measured and compared with controls. Increased mechanical fragility has been observed in congenital hemolytic jaundice, in sickle-cell anemia, and in the presence of cold agglutinins and isoenzymes after agglutination of the cells in the cold, as well as in a few cases of atypical hemolytic anemia in which osmotic fragility was normal or decreased.

Autohemolysis. This test depends on the incubation of sterile defibrinated blood at 37°C for 24 and 48 hr and measurement of the amount of spontaneous hemolysis which occurs. Normally 0 to 0.5 per cent hemolysis takes place in 24 hr, 0.4 to 3.5 per cent in 48 hr. In general, autohemolysis is increased when osmotic fragility is increased and

when there is hemolysis *in vivo*. The procedure may have some value in differentiating certain forms of nonspherocytic hemolytic anemia from hereditary spherocytosis.

Serologic Tests. A simple presumptive test is performed by placing washed red corpuscles from fresh defibrinated blood in each of three test tubes. The first is incubated for 1 to 2 hr at body temperature and then centrifuged. If hemoglobin is present in the supernatant serum, the presence of a warm hemolysin is suggested. The second tube is chilled for 20 min in cracked ice, then incubated for 1 hr and centrifuged. If the result is positive, the presence of a cold hemolysin is indicated. The test tube should be examined before it has been warmed. If only cold agglutinins are present and no hemolysins, it will be seen that the red corpuscles agglutinate in the cold but fail to hemolyze when the tube is warmed, the clumps disappearing instead. When cold agglutinins are present, one must be careful not to shake the cells too much while they are agglutinated in the cold, since they may hemolyze and give a false cold hemolysin test. The blood placed in the third tube is acidified with carbon dioxide. If hemolysis is apparent after incubation for 1 hr and subsequent centrifugation, increased acid hemolysis is suggested. This test is positive in paroxysmal nocturnal hemoglobinuria.

When positive results are obtained in any one of these tubes, the test should be repeated with adequate controls and by the more complete procedures which are available. Thus, if a cold hemolysin appears to be present, the Donath-Landsteiner test should be carried out.

The Coombs antiglobulin test, as already indicated, has proved to be very valuable in helping

to clarify the heterogeneous group of acquired hemolytic anemias. The "direct" Coombs test is carried out simply by mixing the patient's washed red cells with serum from rabbits immunized to human γ -globulin and examining the mixture for agglutination. It serves to demonstrate the presence of "incomplete" antibodies; i.e., those which are attached at some points on the surface of the red corpuscles and require a completing substance, such as antihuman globulin, to cause an agglutination reaction to take place. A positive result has been observed in cases of idiopathic acquired hemolytic anemia, in that type of paroxysmal cold hemoglobinuria which is associated with syphilis, and in many instances of "symptomatic" hemolytic anemia. The test has been negative in most cases of hereditary spherocytosis and is generally negative in sickle-cell anemia and in paroxysmal nocturnal hemoglobinuria, but in hemolytic anemia, because of various physical or chemical agents, it has sometimes been positive.

A positive direct Coombs test is also observed when isoimmunization to known immune bodies has occurred, as in hemolytic disease of the newborn and in sensitization following transfusion. The "indirect" test detects antibodies in the patient's serum. In the indirect test antihuman globulin serum is mixed with normal group O, Rh-positive, and Rh-negative red corpuscles which have been incubated in the patient's serum. The resulting reactions are shown in Table 235-3. If agglutination occurs with both Rh-positive and Rh-negative cells, Rh antibodies can be excluded and the conclusion drawn that circulatory antibodies are present.

In performing the Coombs test it is important that potent antiserum be used and adequate controls

Table 235-3. COOMBS TEST

Hemolytic disorder	Antihuman globulin serum mixed with patient's RBCs (direct)	Antihuman globulin serum mixed with normal RBCs after incubation in patient's serum (indirect)	
		RH +	RH -
Acquired hemolytic anemia:			
With circulating antibodies	+	+	+
Without circulating antibodies	+	-	-
Due to Rh antibodies in Rh+ infant (erythroblastosis fetalis)	+	+	-
Due to physical or chemical agents	±	-	-
Congenital hemolytic anemia (hereditary spherocytosis)* . . .	-	-	-
Sickle-cell anemia	-	-	-
Paroxysmal nocturnal hemoglobinuria	-	-	-
Paroxysmal cold hemoglobinuria (type associated with syphilis) .	+	-	-

* The occasional finding of a positive reaction to the Coombs test in this and in other hemolytic anemias where the test result is usually negative is explained by superimposed, frequently transient episodes of acquired hemolytic anemia.

carried out. False negative results may occur if the red corpuscles have not been washed sufficiently or as a result of a prozone reaction due to inadequate dilution of the serum. Cold hemagglutinins may cause a false positive reaction.

The detailed elucidation of a case of hemolytic anemia of the antibody type will often require the use of still other procedures, but these, in the main, are quite simple. They include (1) the setting up of agglutination tests at various temperatures and in several media, such as isotonic sodium chloride solution and bovine albumin solution, which are helpful in demonstrating and characterizing the agglutinin, and (2) the treatment of the red corpuscles with proteolytic enzymes, such as papain and trypsin, which renders them more susceptible to the demonstration of antibodies. For the antibody tests it is necessary in some instances to use the patient's own red corpuscles rather than any available group O red corpuscles, as is often the practice.

Heinz Bodies. These are intracorporeal structures which probably represent denatured globin derived from hemoglobin in the course of an irreversible reaction with a toxic substance. They appear as refractile, irregularly shaped bodies often lying at or close to the periphery of the red cells, sometimes attached to the outer surface of the cell. They range in size from minute particles to bodies up to $3\ \mu$ in size. Several bodies may be present in the same cell but the largest ones usually appear singly. They are not visible in blood films fixed in methanol and stained with Romanowsky dyes since the bodies and the surrounding hemoglobin stain the same pink color, but they can be stained supravitaly by mixing a drop of blood with 4 drops of 0.5 per cent methyl violet in saline solution or by using a saline solution of brilliant cresyl blue and examining the preparation, after ringing it with petroleum jelly, under the oil immersion lens of the microscope. In methyl violet Heinz bodies stain deep purple; Howell-Jolly bodies, which are always round, and Pappenheimer bodies stain darkly, almost black with a bluish tinge. The reticuloflamentous material of reticulocytes stains a pale blue. In brilliant cresyl blue Heinz bodies stain a distinctly lighter shade of blue than the reticulocyte substance. Heinz bodies can be produced in normal blood by mixing it with acetylphenylhydrazine, but a great many more develop in "primaquine-sensitive" (p. 1291) red cells. In addition, a wide range of aromatic nitrogen compounds of the nitrobenzene series and those related to aniline are capable of producing Heinz bodies. They have also been observed in an obscure type of hemolytic anemia unrelated to exposure to recognized toxic agents ("inclusion body" anemia).

Erythrokinetic Studies. These techniques provide a means whereby erythrocyte production and de-

struction can be quantitated. They also can be used to demonstrate whether the increased blood destruction is due to intracorporeal or extracorporeal causes and to determine if the increased breakdown is occurring mainly in the spleen or elsewhere. As a rule, however, such measurements are not required to arrive at a diagnosis.

Prognosis and Treatment. Prognosis and treatment depend on the nature and cause of the hemolytic disorder. The causative agent, such as a parasite or chemical, if discovered, must be removed. An acute attack of hemolysis requires rest, maintenance of fluid balance, and relief of pain. Blood transfusion may be dangerous if the cause of the hemolysis is extracorporeal and still operating, for then the introduced blood may also be destroyed. Yet, when blood destruction is so acute that hemoglobinemia and hemoglobinuria are present, the possibility of death from circulatory collapse is so great that frequent and sometimes massive blood transfusions must be given.

An important advance in the management of many cases of acquired hemolytic anemia is the discovery that the administration of adrenocorticotrophic hormone (ACTH) or of prednisone or other adrenocorticosteroids will control the hemolytic manifestations. The latter are preferable since they can be given orally. As much as 60 to 100 mg prednisone per 24 hr may be required. In some instances transfusion can be withheld entirely, while in other cases, where the anemia is so severe that transfusion is necessary, blood can be given with much less chance of a reaction if steroid therapy has been started. As in the treatment of other disorders, the usual precautions, such as salt restriction and administration of potassium chloride, should be taken when these agents are used in the treatment of hemolytic anemia.

Splenectomy, while almost invariably beneficial in hereditary spherocytosis, is much less successful in the acquired forms. Furthermore, if carried out in an acute hemolytic phase, the operative mortality is high. In idiopathic acquired hemolytic anemia, therefore, the hormones should be used first, at least in preparation for operation. Unfortunately, neither splenectomy nor hormone therapy is permanently helpful in all cases; in many the evidence of hemolysis returns when hormone therapy is interrupted.

In some cases of "symptomatic hemolytic anemia" treatment of the underlying disorder, when possible, relieves the hemolytic anemia as well. When this does not occur, a trial of steroid therapy is justified. In certain instances splenectomy may be helpful, especially if leukopenia and thrombocytopenia are also present and the picture is that of "hypersplenism."

Splenectomy is of no value in sickle-cell anemia,

thalassemia, or paroxysmal nocturnal hemoglobinuria.

Paroxysmal Cold Hemoglobinuria

This is an uncommon disorder characterized by the sudden passage of hemoglobin in the urine, following local or general exposure to cold. Aching and pain in the back, legs, or abdomen, and other symptoms of acute hemolysis, such as a chill, fever, and malaise, are associated with the passage of dark brownish urine. Other findings are those characteristic of acute hemolytic anemia. Symptoms may appear at any time from a few minutes to 7 or 8 hr following exposure.

Donath and Landsteiner showed that the hemoglobinuria is due to the sudden intravascular hemolysis of blood as the result of the action of an autohemolysin contained in the patient's blood. The hemolysin unites with the red corpuscles only at a low temperature, but destruction of the corpuscles occurs only after the temperature of the blood has returned to body temperature. Appropriate tests have been devised to demonstrate such a cold hemolysin. At the time of hemolytic attacks produced by chilling, strongly positive direct agglutinin (Coombs) reactions have been observed, but they become negative after the attacks. The typical condition is a manifestation of syphilis, the congenital form particularly, and thorough antisyphilitic therapy ends the clinical manifestations.

A number of cases have been described, however, in which indications of syphilis were lacking even though, in some of the cases, the Wassermann reaction was positive. Since false positive Wassermann and Kahn reactions are not uncommon in acquired hemolytic anemia of the autoantibody type, it has been suggested that paroxysmal cold hemoglobinuria is not exclusively a manifestation of syphilis and that some of the cases regarded as the typical condition of syphilitic origin may well have been examples of autoimmune hemolytic disease of the cold antibody type.

Chronic Hemolytic Anemia with Paroxysmal Nocturnal Hemoglobinuria (Marchiafava-Micheli Syndrome)

This is a rare disorder of insidious onset which is characterized by signs of hemolytic anemia and is marked by attacks of hemoglobinuria which occur chiefly at night. The symptoms are those of long-standing anemia, but there may be abdominal, lumbar, or substernal pain, which often ushers in an attack of hemoglobinuria. The findings are similar to those in other hemolytic anemias and include splenomegaly and well-marked anemia. The osmotic fragility of the red corpuscles is normal and spherocytosis is not characteristic.

There may be hemoglobinemia even when there is no hemoglobinuria. Leukopenia is usual and may be marked, and there may be thrombocytopenia; the pancytopenia may, in fact, lead to an erroneous diagnosis of aplastic anemia. The urine contains increased amounts of urobilinogen as well as hemoglobin. Hemosiderin can often be demonstrated in the leukocytes or epithelial cells of the urine.

The fault appears to reside in the red corpuscles, which are unusually susceptible to acid hemolysis. A simple test for this has been described already (p. 1293). It has been suggested that the destruction of the cells is promoted by the accumulation of carbon dioxide during sleep, an optimum acid pH being required for hemolysis to take place. The latter has been shown to be brought about by the action of the *properdin system*. The components of this system are properdin (a protein), Mg^{++} , and cofactors resembling complement, all of which are normal constituents of plasma. Normal human red cells are not damaged by this system. The defect in PNH (paroxysmal nocturnal hemoglobinuria) red corpuscles which renders them susceptible to the properdin system may possibly reside in the lipid pattern of the lipoproteins of their stroma.

This disorder does not appear to be hereditary. Treatment is purely symptomatic. Splenectomy is of no value. The intensity of the hemolytic process varies; crises of severe anemia may occur. Transfusion of plasma usually precipitates hemolytic crises, but saline-washed red corpuscles can be given with impunity. Although thrombocytopenia is common, purpuric or hemorrhagic manifestations are unusual; in fact, thrombotic complications are not infrequent. It has been found that the anticoagulant dicoumarin (Dicumarol) impedes hemolytic activity in this disease, but this drug is chiefly of importance in order to prevent thrombotic complications. Infections are frequent in these patients, partly, perhaps, because of the associated leukopenia. Prognosis varies greatly. Although a fatal termination may ensue in several years, in some cases the disorder has been compatible with life for many years.

Hereditary Spherocytosis (Chronic Acholuric Jaundice, Spherocytic Anemia, Chronic Familial Icterus, Congenital Hemolytic Jaundice)

Definition. This is a familial and hereditary disorder characterized by spherocytosis, increased osmotic fragility of the red corpuscles, splenomegaly, and a variable degree of hemolytic anemia.

History. Chiefly as the result of the observations of the French school, during the early part of the present century this familial disorder was clearly defined, becoming known as the type of Chauffard and Minkowski. It was distinguished from the ac-

quired form of hemolytic anemia of Hayem and Vidal.

Etiology. Transmitted as a mendelian dominant trait by either parent, this disorder is due to an inherited defect of the red corpuscles, which tend to be more spheroid than normal and thus are more subject to destruction. The significance of spheroidicity of the red corpuscles and of increased osmotic fragility and the role of the spleen have been discussed already (p. 1292).

Morbid Anatomy. The spleen is greatly enlarged, often weighing 1,000 to 1,500 Gm. The pulp and, to a lesser extent, the sinuses are greatly congested. Depending on the degree of anemia and the extent of blood destruction, hyperplasia and even metaplasia of the bone marrow occur, and deposits of iron pigment are found in the liver, kidneys, and even lymph nodes.

Symptoms. Jaundice and splenomegaly are the most common manifestations and may pass unnoticed for many years. A persistent sallow appearance rather than obvious jaundice may be present. Symptoms of anemia are usually absent or mild. At any time from birth to late adult life, attention may be drawn to the disorder by the *crise de déglobulisation*, which is characterized by fever, lassitude, palpitation, and shortness of breath or even violent abdominal pain, vomiting, and anorexia. Rather than being episodes of increased blood destruction, as has always been assumed, these crises have been observed by several investigators to be associated with sudden temporary cessation of blood formation. Since the life span of the red corpuscles of congenital hemolytic icterus is very brief, anemia develops rapidly under these circumstances. It remains to be shown how often such a mechanism, rather than hemolysis, is the cause of the crises which occur in this disease.

The liver may or may not be enlarged. Developmental anomalies are often present. A chronic leg ulcer may be found. Cholelithiasis is a frequent complication, and symptoms due to this cause may first bring the patient to the physician.

The anemia is usually moderate in degree, but may be very mild or severe. It is normocytic or simple microcytic in type but, when severe and associated with marked reticulocytosis, it can be macrocytic. There is little poikilocytosis, but small, bright, deeply staining red corpuscles (spherocytes) are often seen scattered among the cells of normal size. Reticulocytes are characteristically increased in number, most often numbering 5 to 20 per cent. Polychromatophilia and normoblasts may be seen in the blood smear. The leukocytes are usually normal in number or slightly increased. The platelet count is generally normal.

Increased osmotic fragility of the red corpuscles

is characteristic. Hemolysis beginning at 0.64 per cent saline solution is not unusual and may be complete at the point where hemolysis normally begins.

Bilirubinemia of the "indirect" type and increased quantities of urobilinogen in the urine and stools, without bile in the urine (acholuric), are the characteristic changes in pigment metabolism.

Diagnosis. Splenomegaly, icterus of the hemolytic type, reticulocytosis, increased osmotic fragility, and presence of the anomaly in other members of the family are the characteristic findings. The Coombs test is negative except in occasional cases. In these it is likely that a superimposed acquired immunohemolytic process has developed. When the picture is not entirely typical, a careful study to rule out other types of hemolytic anemia must be made, as outlined previously.

It is especially important to distinguish cases of *congenital nonspherocytic hemolytic anemia*, because they have not been benefited by splenectomy. Although such cases resemble hereditary spherocytosis in their mode of inheritance, they differ in that the anemia is generally macrocytic, there is often a moderate degree of ovalocytosis, and sometimes there is conspicuous punctate basophilia. Spherocytes are not found, and osmotic fragility is normal. The reported cases have not been identical in all respects, however, and probably represent several different disorders. This statement is based on observation of morphologic differences, such as the presence of crenated and irregularly contracted corpuscles in some cases, Pappenheimer bodies in others, extreme variation in red cell size and shape in still others, and even increased resistance to saline hemolysis and the presence of target cells, as found in certain abnormal hemoglobin disorders. It has been shown that the reversibility of the metabolic lesion by adenosine, observed in certain cases of hereditary spherocytosis, did not occur in congenital nonspherocytic hemolytic anemia. Studies of autohemolysis have revealed at least two forms of the nonspherocytic disorder.

Treatment. This is the one disorder in which splenectomy is associated with consistently satisfactory results. The operation is indicated in every patient in whom clinical manifestations are present. Although remissions develop and latent periods of many years' duration may occur, spontaneous recovery does not take place. At operation, a careful search should be made for accessory spleens, and they should be removed if found. Following operation, anemia, jaundice, and reticulocytosis disappear. The osmotic fragility of the red corpuscles, however, as well as the spherocytosis, may persist.

During a crisis, repeated blood transfusions must be given.

SICKLE-CELL ANEMIA AND OTHER
ABNORMAL HEMOGLOBIN SYNDROMES

Definition. Sickle-cell anemia is a hereditary and familial hemolytic anemia, essentially peculiar to Negroes and characterized by the presence of red corpuscles which, under appropriate conditions, assume sickle-shaped or oat-shaped forms.

Etiology. Just as hereditary spherocytosis is rare in the Negro, sickle-cell anemia is extremely rare except in Negroes or when mixture with Negro blood has occurred. The anomaly appears to be inherited as a mendelian dominant characteristic. Inheritance of the abnormality from only one parent, the heterozygous state, is represented by the sickle-cell trait, in which sickling of the red corpuscles can be demonstrated but is not accompanied by symptoms of anemia. Sickle-cell anemia is the homozygous state in which one abnormal gene has been inherited from each parent. Sickle-cell anemia possesses all the characteristics of a chronic hemolytic anemia with certain special features as well.

From time to time exception has been taken to the heterozygous-homozygous theory described above because of certain family studies which failed to demonstrate the sickle-cell trait in both parents of children with sickle-cell anemia and also because certain cases were observed which seemed to be intermediate in their clinical manifestations between those of the severe hemolytic anemia of sickle-cell anemia and the asymptomatic state, the sickle-cell trait. The discovery of abnormal hemoglobins other than sickle-cell hemoglobin has offered a reasonable explanation for these seeming exceptions.

The discovery by Pauling and his associates that the electrophoretic mobilities of sickle-cell anemia (S) and normal hemoglobin (A) differ led to establishment of the principle that a molecular abnormality in a single protein may cause a sequence of events such as that which characterizes the complex disease, sickle-cell anemia. It was shown that in a buffer of suitable pH, the two components of a mixture of normal and sickle-cell hemoglobin migrate in opposite directions. Since the heme moiety is the same in sickle-cell and in normal hemoglobin, the electrophoretic differences were attributed to differences in the globin portion.

These investigations were the first of an ingenious series of studies carried out with the aid of paper, starch gel, and other techniques for electrophoresis, and by means of ion exchange chromatography and various procedures for the study of protein structure. As a result it has been learned that the globin of normal adult hemoglobin is made up of two pairs of polypeptide chains, each containing about 150 amino acids, now termed the alpha and beta chains.

Fetal hemoglobin is composed of two alpha chains and two different chains, termed gamma chains. A very small quantity of the latter persists, even in adult life. Still another polypeptide chain is found, in small quantity, in normal adult hemoglobin. This has been designated the delta chain: two alpha and two delta chains make up the so-called normal A₂ hemoglobin.

The application of the above techniques has uncovered a large number of "abnormal" hemoglobins which differ from normal hemoglobin in one or more of several ways; namely (1) replacement of one amino acid by another in the normal amino acid sequence of one of the peptides separated from the α or β polypeptide chains; (2) replacement of certain normal chains by other apparently normal chains; (3) absence of certain peptides.

Thus, hemoglobin S differs from hemoglobin A in that valine replaces a glutamic acid in peptide 4 of the β chain. In hemoglobin C, lysine rather than valine replaces the same glutamic acid. In the type of hemoglobin G first found in San José, glycine replaces a different glutamic acid in the same peptide. Hemoglobin E differs from hemoglobin A in that lysine replaces a glutamic acid in peptide 26 of the β chain. In hemoglobin I glutamic acid replaces lysine in peptide 23 of the α chain. Hemoglobin H differs from all others in that it is composed of four β chains. Hemoglobin Bart's, on the other hand, is made up entirely of γ chains. In one form of hemoglobin D, peptide 26 of the β chain is absent. Other examples could be cited.

The number of abnormal hemoglobins is constantly increasing. In addition, various combinations of normal and abnormal polypeptide chains, or combinations of two or more abnormal polypeptide chains may occur, as well as combinations of various abnormal hemoglobins with the thalassemia trait (p. 1302). These discoveries are of great interest and importance in human genetics and anthropology. However, only a limited number of abnormal hemoglobins are associated with clinical manifestations. Some of these are presented in Table 235-4.

It is natural that problems should have arisen in developing a suitable terminology for the abnormal hemoglobins. To distinguish it from normal adult hemoglobin (A) and from sickle-cell hemoglobin (S), the third type of adult hemoglobin which was found was named C. The succeeding letters of the alphabet were given to other hemoglobins, as they were uncovered, except for F, the letter reserved for fetal hemoglobin. However, as abnormal hemoglobins have been discovered in different parts of the world, the same letter has been given to more than one hemoglobin. This has led to the practice

FIG. 235-3. Relative mobilities of normal and abnormal hemoglobins on paper electrophoresis at pH 8.6. The mobility of hemoglobin M (Chap. 237) is similar to that of normal hemoglobin (hemoglobin A). Other hemoglobins can be classified as *slow* (e.g., hemoglobin S, this group includes the D hemoglobins and Stanleyville II), *very slow* (e.g., hemoglobin C; this group includes the normal hemoglobin A, as well as the abnormal hemoglobins E and O), or *moderately slow* (e.g., the G hemoglobins, this includes L, P, Q, Lepore (Le), and Stanleyville I). In addition, there are *fast* hemoglobins with electrophoretic mobilities faster than that of hemoglobin A. These include H, I, J, K, N, Norfolk, and Hopkins-1 and Hopkins-2. (Wintrobe: "Clinical Hematology," 5th ed., Philadelphia, Lea & Febiger, 1961.)

of designating the abnormal hemoglobin according to the geographic area where it was first discovered, as well as by a letter; for example, $G_{San\ Jose}$, G_{London} . With advances in knowledge concerning the chemical constitution of the various hemoglobins, more exact terminology will undoubtedly be adopted; e.g., $\alpha_2^A \beta_2^B$ for that found in sickle-cell blood to indicate the polypeptide chain in which the abnormality resides. Quite possibly, even more specific designation will be adopted. For the purposes of the following discussion, however, these details are not essential.

Sickle-cell anemia was first described in Negroes in North America. In Africa a broad belt with high incidence of the sickling trait extends roughly across the middle third of the continent, the highest figures being in eastern and central Africa. The sickling trait, however, does not seem to be present exclusively in the Negroes of Africa or in Negroes of African origin. It has been discovered in certain aborigines in southern India and southern Arabia as well as in Greece and southern Turkey. Instances of "sickle-cell anemia" described so far in white persons have been mainly in those of Greek or Italian stock. These cases, it now appears, are examples of admixture of the sickling and the thalassemia traits, not of homozygous sickle-cell disease.

The incidence of hemoglobin C is highest in West Africa. Surveys of randomly selected Negroes in the United States have yielded values of 2 to 3 per cent, as compared with 85 per cent for hemoglobin S. Hemoglobin D has been found in, at most, 0.4 per cent of American Negroes and may well have originated in non-Negroes. Actually nine types

of hemoglobin D have been found. Hemoglobin E is present in large numbers of Thais (136 per cent) and Cambodians (35 per cent) and appears to be a characteristic of the peoples of southeast Asia. It has been encountered frequently in association with the gene for thalassemia. Nine hemoglobins G have been described; all are rare. Hemoglobin H is the first of a series of "fast" hemoglobins, so called because their anodal mobility in paper electrophoresis at pH 8.6 is faster than that of normal hemoglobin. Other "fast" hemoglobins include I, J, K, and N. Still other abnormal hemoglobins have been described: hemoglobins L, O, P, Q, Lepore, Stanleyville I and II, Hopkins-1 and -2, Norfolk, F and P or Singapore-Bristol, Bart's, and Alexandra. The electrophoretic mobilities of a number of the abnormal hemoglobins are illustrated diagrammatically in Fig. 235-3.

Pathology. In sickle-cell anemia, in addition to the signs of a chronic hemolytic anemia (normoblastic hyperplasia of the bone marrow, hemosiderosis), evidence of thrombosis, infarction, necrosis, or hemorrhage may be present, especially in the lungs, spleen, and nervous system. The spleen may be shrunk to a tiny, wrinkled mass.

Symptoms. In sickle-cell anemia, jaundice and a chronic anemia with few or no complaints are interrupted by periods of increased weakness, episodes of aching pain in the joints or elsewhere in the extremities, or sudden attacks of severe abdominal pain which have often been mistaken for ruptured peptic ulcer, intestinal obstruction, or some other abdominal emergency.

The victims of sickle-cell anemia are often poorly developed, and bony deformities of various types may be discovered. The scleras are icteric, and there may be slight general glandular enlargement, but splenomegaly is encountered in only about 15 to 20 per cent of cases. The heart may be enlarged, and the physical signs may closely simulate those of mitral stenosis due to rheumatic fever. Hyposthenuria is common. In many instances chronic leg ulcers are found over the internal or external malleoli. Roentgenograms may reveal radial striation in the skull, osteoporosis in the vertebral bodies, or other changes in the long bones. Osteomyelitis is a not-infrequent complication.

The anemia is usually surprisingly severe, erythrocyte counts below 2.5 million being common. The anemia may be normocytic or macrocytic. Oval, cigar-shaped, or other bizarre forms of red corpuscles may be seen in the stained blood smear. The sickling is brought out clearly in wet films of blood which have been fixed under a cover glass and sealed with paraffin. In cases with sickle-cell anemia the typical sickled and oat-shaped forms with elongated, pointed filaments appear within a few hours. When only the sickle-cell trait exists, 24

hr is often required to produce this change and only a proportion rather than practically all of the cells are affected. By the use of reducing agents such as sodium bisulfite, sickling can be hastened and the characteristic forms appear promptly.

In sickle-cell anemia, reticulocytosis, polychromatophilia, normoblasts, leukocytosis with "shift to the left" in the myeloid series, and an increase in platelets are found as well as hyperbilirubinemia and increased urobilinogen in the urine and stools. Osmotic fragility is decreased, not increased. The bone marrow shows striking normoblastic hyperplasia.

Carriers of hemoglobin C are asymptomatic, but target corpuscles are found characteristically in their blood. The homozygous state, hemoglobin C disease, is associated with symptoms similar to those of sickle-cell anemia but in general much milder. Anemia is common but usually of moderate degree, normocytic or microcytic in type, and accompanied by slight bilirubinemia. Under conditions which permit partial drying and partial hemolysis, crystallization of hemoglobin C occurs *in vitro* when the concentration of the abnormal hemoglobin in the red cells is sufficiently great.

A number of instances have been discovered in which both S and C hemoglobin were demonstrated. The combination of hemoglobin C with S hemoglobin is accompanied by sickling of the red corpuscles as well as by a hemolytic syndrome similar to sickle-cell anemia but differing in that the hemolytic anemia is milder, target cells are more plentiful in the blood, and there is slowly progressive splenomegaly. It is very probable that most of the cases formerly reported as forms of sickle-cell anemia intermediate between the asymptomatic carrier state and the homozygous classical disease were actually cases simultaneously heterozygous for S and C hemoglobin.

Of the other abnormal hemoglobin syndromes, as outlined in Table 235-4, few are associated with clinical manifestations unless they occur in combination with hemoglobin S or the thalassemia gene. Hemoglobin E disease, the homozygous EE state, is characterized as a rule by mild microcytic, normochromic anemia and minimal signs of hemolytic anemia. Target cells are plentiful. The size of the spleen is normal or only slightly enlarged. Hemoglobin H is unique in that it has been demonstrable only when it was accompanied in the same individual by another genetic anomaly of hemoglobin formation, the thalassemia gene or a closely related disorder. Clinical manifestations suggest thalassemia but spontaneous denaturation of hemoglobin H within intact erythrocytes *in vitro* results in formation of multiple inclusion bodies.

Diagnosis. Sickle-cell anemia is often mistaken for some other disease. Rheumatic fever, peptic

ulcer, renal or biliary calculus, osteomyelitis, and various neurologic disorders may be simulated. Recognition depends on the demonstration of sickling and the finding of anemia of the hemolytic type.

In distinguishing persons with the sickle-cell trait who may have some disorder accompanied by anemia from those who have sickle-cell anemia, it must be kept in mind that the former may develop any type of anemia, while in the latter the anemia is always hemolytic in type.

Some of the distinguishing features of the other hemoglobinopathies and of disorders resulting from combinations of the sickle-cell gene with the genes for other abnormal hemoglobins or with the thalassemia gene have been discussed already and are summarized in Table 235-4. The proportions of target cells present, the finding of intraerythrocytic crystals, or the demonstration of inclusion bodies in the red corpuscles gives clues concerning the nature of the disorder in question. Paper electrophoresis (Fig 235-3) and the alkali denaturation procedure for the demonstration of hemoglobin F are simple and essential additional procedures which should be employed. For the elucidation of the more unusual syndromes, the cooperation of a laboratory is needed where special techniques for the study of the abnormal hemoglobinopathies are available.

Treatment and Prognosis. Since these abnormal hemoglobin syndromes represent inherited anomalies of hemoglobin formation, it is apparent that no treatment other than symptomatic therapy can be provided. No method is known whereby the abnormal state can be altered. Fortunately a number of these conditions are asymptomatic. Sickle-cell anemia, however, is a serious disease which is ultimately fatal, often before the age of thirty. Death may result from intercurrent infection, renal or cardiac failure, thrombosis or hemorrhage involving vital tissues, or it may follow one of the abdominal crises. Blood transfusions are of little value except in the abdominal crisis if shock is present. Antianemic agents are of no value and splenectomy also has no place in therapy.

The prognosis of hemoglobin C disease is good but that of sickle-cell-hemoglobin C disease is less favorable, although usually much better than that of sickle-cell anemia. As in that disease, acute infarction of the bone marrow and fat embolization play an important role in the pathogenesis of many of the acute manifestations of the disorder. Aseptic necrosis of the femoral heads is a curious complication. The morbidity and mortality during pregnancy are usually great in hemoglobin S-C disease.

Pathogenesis. The ratio of sickle-cell hemoglobin to normal hemoglobin in the blood of individuals with the sickle-cell trait has been found to vary

Table 235-4. SUMMARY OF USUAL FINDINGS IN ABNORMAL HEMOGLOBINOPATHIES AND THALASSEMIA

Condition	Hb types ¹	Sickling	Microcytosis	Hypo-chromia	Target cells ² , %	Hemolytic anemia ³	Spleno-megaly

¹ The major hemoglobin component is shown first. In sickle-cell anemia especially, there may also be a substantial proportion of Hb F.

² Osmotic fragility is reduced more or less proportionately to the number of target cells.

³ Mechanical fragility and RBC survival correspond as a rule to the presence and degree of hemolytic anemia.

⁴ Chiefly in Negroes.

⁵ Cases of sickle-cell anemia intermediate in severity between sickle-cell trait and sickle-cell anemia.

⁶ Sickle-cell disease in Caucasians.

⁷ Or polycythemia with microcytosis.

⁸ In the majority of cases.

⁹ Partial drying and partial hemolysis are associated with crystallization of hemoglobin. Rod-shaped erythrocytes with squared corners are seen in blood smear.

¹⁰ Inclusion bodies demonstrable in red corpuscles.

¹¹ No clearly defined hematologic abnormalities have been reported to be associated with the inheritance of the following traits: J, K, L, N, O, P, Q. The manifestations of the Lepore trait are like those of thalassemia minor; when Lepore is associated with the thalassemia trait, the clinical picture is that of thalassemia major.

¹² Basophilic stippling of the red corpuscles.

from 22 to 45 per cent, while the amount in the blood of those with sickle-cell anemia has ranged from 76 to 100 per cent. The variations in the amount of sickle-cell hemoglobin have been explained on the ground that the expression of the S gene may be under the modifying influence of other genetic factors; the lower and higher proportions of S hemoglobin are a familial characteristic.

Hemoglobin S is relatively insoluble. The sickling process seems to be best explained on the assumption that in the oxygen-unsaturated state the S

hemoglobin molecule undergoes orderly orientation, forming, by specific linkage of the individual molecules, long chains of hemoglobin elements. Subsequent parallel alignment of these elements results in birefringent tactoids, the sickled cell being a hemoglobin tactoid, thinly veiled and somewhat distorted by the cell membrane. The clinical and hematologic manifestations and the pathologic changes found in sickle-cell anemia can be explained by the peculiar physical properties of the sickle cell. The intracellular molecular orientation

produces the sickled form of the erythrocyte. At decreased oxygen tensions the viscosity of the whole blood and the mechanical fragility of the erythrocytes are significantly increased, owing to the assumption of the sickled form. With the increase in viscosity, a cycle is initiated in which the factors of stasis, lowered pH, and continuing oxygen uptake combine to augment the number of sickled cells and prolong the stasis. Plugs or masses of sickled erythrocytes become solid enough to occlude vessels, resulting in the "thrombotic" episodes associated with pain which are characteristic of the disease. Erythrostasis limits access to cell-maintaining energy and also favors the sickled state. When red cells after stasis are released into free circulation, a certain proportion, having been fixed in irreversible sickled form, have also become more fragile in terms of mechanical trauma. Consequently, they are more than normally susceptible to the trauma associated with circulation. Increased blood destruction is the result. The development of these changes depends on the quantity of abnormal hemoglobin present; it is assumed that in the homozygous state the erythrocytes contain sufficient abnormal hemoglobin to result in sickling within the physiologic range of oxygen tensions. It is noteworthy that, although the heterozygous state is ordinarily benign, splenic infarction has been observed in a number of persons with the sickle-cell trait who were subjected to conditions of greatly reduced oxygen tension.

Many of the clinical manifestations of sickle-cell anemia can be explained on the basis of obstruction of vascular channels by tangles of sickled erythrocytes. Thus, the picture of shock presented by patients with the abdominal crisis of sickle-cell anemia may be due to the packing of sickled erythrocytes in small capillaries, thus removing them from a functional status and adding to the anemia already present. The capillary hypoxemia would result in plasma loss, hemoconcentration, and further stagnation. Bone pain may be due to distention of the intramedullary cavity of the bones by the vascular engorgement. In some cases there may be focal infarction of bone marrow. It is possible that the irregular sclerosis visible in roentgenograms of the long bones is due to healing of such infarcted areas with scarring and subsequent osteoid deposition. Other changes in the bones may perhaps be the result of hyperplasia compensatory to the increased blood destruction.

THALASSEMIA (Cooley's Anemia, Erythroblastic Anemia, Mediterranean Anemia, Target-cell Anemia, Familial Microcytic Anemia)

Definition. An inherited disorder originally seen, in particular, in individuals living in countries bor-

dering the Mediterranean or in their offspring elsewhere, which is characterized by the presence of unusually thin red corpuscles, microcytosis, various degrees of anemia, and, when the anemia is severe, numerous nucleated red corpuscles. This concept of thalassemia has now been broadened, as will be described below.

History. Cooley and Lee (1925) described a chronic progressive anemia commencing early in life, which was associated with a characteristic facies, splenomegaly, and a familial and racial incidence. Later it became clear that this was the severe and fatal form of a disorder which in milder form is seen in adolescents and in adults.

Etiology. Those first discovered to be affected were chiefly of Italian, Greek, Syrian, or Armenian parentage. In certain communities of Italians, the anomaly has been observed in as many as 20 per cent of those examined. The disorder is presumed to be due to the inheritance of a factor which leads to an anomaly of red corpuscle production. While there is in this condition a disturbance in iron metabolism, the primary defect appears to be in hemoglobin synthesis. It was found that the red corpuscles in this disorder contain a variable and often large proportion of fetal hemoglobin, as indicated by the high resistance of the hemoglobin to denaturation in aqueous alkaline solutions as well as by other physical properties. In the severe form of the disease, the electrophoretic pattern of the hemoglobin resembles a mixture of normal and fetal hemoglobin. This led to the suggestion that the gene governing this disorder blocks the production of normal hemoglobin and causes the production of fetal hemoglobin as a compensatory phenomenon. The mode of inheritance is that of a recessive trait. In the heterozygous state, when only one allele is inherited (thalassemia minor), the interference with hemoglobin synthesis is not serious. In the homozygous condition, when two alleles are inherited, one from each parent (thalassemia major), there is a drastic reduction in normal hemoglobin production.

Subsequent studies showed that thalassemia affects many of the peoples of the Eastern Hemisphere and that a whole spectrum of disorders can be included under this heading. Not only is this trait encountered in the Mediterranean basin, but a high incidence occurs in Thailand and elsewhere in the Far East. Furthermore, the range of severity is much broader than defined by the above two categories, thalassemia minor and thalassemia major.

Three observations have proved of great importance in the elucidation of the thalassemia states. First is the demonstration by starch block electrophoresis of a component of normal hemoglobin, A_2 , which moves more slowly than the major com-

ponent of normal adult hemoglobin. This is thought to be composed of two α polypeptide chains and a pair of distinctive chains, termed δ chains. In the majority of persons with the thalassemia trait the quantity of hemoglobin A_2 is greater than normal (i.e., above 2.54 ± 0.35 per cent). However, a minority are found without such an increase. In some individuals with normal or low hemoglobin A_2 there has been evidence of double heterozygosity for thalassemia and hemoglobin H, hemoglobin I, or some other, unidentified abnormal hemoglobin.

It has been noted, in addition, that in some instances of thalassemia major, the production of normal adult hemoglobin is suppressed. Again, as already mentioned, fetal hemoglobin is found in increased amounts. However, in thalassemia minor, the amount of hemoglobin F is normal or minimally elevated as a rule; yet, in several instances, large amounts of hemoglobin F have been demonstrated. In these and other observations support is found for the concept that there are several varieties of thalassemia. In addition, there are the cases in which the thalassemia trait is clearly associated with one of the abnormal hemoglobins, such as S, C, E, and H. It is possible that hemoglobin A_2 is inherited as an independent system, and this may be true also of hemoglobin F. A specific thalassemia hemoglobin abnormality has not been identified, but it is conceivable, at least, that such an abnormality exists but has remained in hiding because the aberrant amino acid sequence may be of such a nature that the hemoglobin produced is electrophoretically normal. In essence, then, the spectrum of disorders which has been included under the designation of thalassemia, as recognized clinically, may represent a great variety of inherited abnormalities, joined in various combinations.

Symptomatology. The full-blown disorder (*thalassemia major*, *Cooley's anemia*) develops insidiously within the first year or two of life, perhaps at birth, and is marked by pallor and great enlargement of the spleen and even the liver. The appearance of the child is often mongoloid. Roentgenograms reveal great thickening of the diploe of the skull with perpendicular striation, increase in the medullary portion of the long bones with thinning of the cortex, and other changes attributable to the extreme hyperplasia of the bone marrow. Anemia is severe, hypochromic and microcytic in type, and the red corpuscles contain so little pigment and are so thin that their "buckling" produces forms which have the appearance of targets. Fragility tests in hypotonic saline solutions reveal that the corpuscles are unusually resistant to hemolysis by this means. Normoblasts and microblasts, as well as polychromatophils, basophilic stippling, Howell-Jolly bodies, and moderate reticulocytosis, in addition to

leukocytosis (19,000 to 25,000 per cu mm) with "shift to the left," reflect the myeloid hyperactivity. There is usually slight or moderate bilirubinemia, with a corresponding increase in the urobilinogen content of the urine and stools.

Thalassemia minor may pass entirely unnoticed, painstaking examination may be necessary to reveal any abnormality. Slight anemia, splenic enlargement, microcytosis and hypochromia, target cells, poikilocytosis out of proportion to the existent anemia, decreased hypotonic saline fragility, basophilic stippling of the red corpuscles, and bilirubinemia are some of the signs which, singly or in various combinations, mark this disorder. Roentgenographic changes in the bones similar to, though less pronounced than, those found in the severe form may be observed.

The term *thalassemia minima* has been applied to instances in which manifestations are very slight. Additional designations and clinical subdivisions have been proposed for other variations of the clinical picture, since such a wide range is observed. Little is to be gained from such a classification, however. *Microdrepanocytic disease* is the name given to the combination of sickle-cell and thalassemia genes which results in a chronic hemolytic anemia with some of the characteristics of both sickle-cell disease and thalassemia.

Diagnosis. The various forms of congenital hemolytic anemia, as well as plumbism and other acquired forms of "refractory" anemia, must be distinguished from thalassemia. The clinical and hematologic manifestations of some of the hemoglobinopathies which may be associated with thalassemia are presented in Table 235-4. Thalassemia minor and minima have occasionally been confused with polycythemia vera because the erythrocyte count may be greater than normal. However, in such cases the hemoglobin and volume of packed red cells are usually slightly below the average normal values since the red corpuscles are microcytic and hypochromic.

Prognosis. The severe form is fatal. Prognosis is more grave the earlier the disease becomes manifest. Less severe forms are compatible with life, and the mildest forms may even have no influence whatever on life span.

Treatment. With the exception of the rare forms of hypochromic, microcytic anemia which were discussed earlier (p. 1280), this is the only form of hypochromic microcytic anemia in man which does not respond to iron therapy. Splenectomy is of no value, as a rule, nor are any other measures now known.

Pathology. Evidences of pronounced myeloid hyperplasia, both medullary and extramedullary, the effects of such changes on the bones, and deposits of iron-containing pigment in the liver, pan-

creas, and other tissues are the most significant findings.

ANEMIAS ASSOCIATED WITH INFECTIONS AND VARIOUS OTHER DISORDERS, CHIEFLY CHRONIC

In the preceding sections, anemia resulting from blood loss, as well as anemias due to excessive blood destruction and those associated with deficiency of certain factors concerned in erythropoiesis, were discussed. The characteristics of these anemias are, in the main, well defined, and much has been learned in recent years about their pathogenesis. The hemolytic anemias and the specific nutritional deficiency anemias are, however, relatively uncommon. Far more frequent in occurrence and yet much less well understood are the anemias associated with various chronic disorders and with infection. Such anemia is usually only moderate in degree; hemoglobin values of 13 to 10 Gm per 100 ml of blood are seen more frequently than lower values. The anemia is usually normocytic, and in the smear the red corpuscles generally show little abnormality in size or shape, a monotonous picture unaccompanied by polychromatophilia, basophilic stippling, or nucleated red corpuscles. Exceptions are found in *lead poisoning*, where basophilic stippling is characteristically seen; in the so-called *myelophthistic anemias*, such as those associated with metastases to the bone marrow, leukemia, multiple myeloma, or myelosclerosis; and in severe renal disease. There, often corresponding rather closely to the gravity of the renal disorder, as manifested by the degree of retention of nitrogenous and other waste products, hemoglobin values as low as 5 Gm per 100 ml are found; and the blood smear may reveal normoblasts, stippling, and moderate anisocytosis and poikilocytosis. The anemia may be somewhat microcytic or hypochromic, and occasionally is macrocytic. If the renal disease has been insidious in onset and is chronic in type, the clinical manifestations and the anemia may be quite confusing unless one is aware that striking degrees of anemia may be encountered in the absence of impressive signs of renal disorder.

The bone marrow in these conditions shows nothing characteristic. The nucleated red corpuscles are of the normoblastic type. The marrow may appear hyperplastic, normal, or hypoplastic. Hyperplasia of the leukopoietic tissue is found if the disorder is one which calls forth a leukocytic response.

The pathogenesis of the anemia in these conditions has been discussed elsewhere (p. 206). It seems likely that some fault in the construction of red corpuscles is an important underlying mech-

anism in their development. In any event, the impact of infection on erythropoiesis is such that no form of antianemic therapy, such as the administration of vitamin B₁₂ or of iron, has any influence. The anemia disappears spontaneously if the infection is successfully treated, or subsides as the result of the defense reactions of the host. Similarly the anemia of renal insufficiency is closely tied with the underlying disorder and is generally not influenced by measures other than those which affect renal function.

It is both interesting and curious, therefore, that the oral administration of *cobaltous chloride*, in doses ranging from 20 to 160 mg per day, generally in the form of 20-mg-size, enteric-coated tablets taken with meals, has been observed to produce a modest reticulocytosis and a significant moderation in the degree of anemia both in cases of anemia accompanying chronic infection and in that associated with renal disease. In the latter, appetite may improve and there may be increased tolerance for the medications necessary to correct electrolyte abnormalities. There is no evidence that cobalt therapy alters the course of renal disease, and the hemoglobin has been found to return to pretreatment levels after cobalt administration has been discontinued. The mode of action of cobalt is obscure, but it is generally assumed that it serves as a nonspecific erythropoietic stimulant rather than as a specific nutritional component required for red cell or hemoglobin production.

Malignant disease is not necessarily accompanied by anemia. Anemia accompanies malignancy in the alimentary tract more often than elsewhere. In such cases nutritional deficiency may play an important role in the pathogenesis of the anemia, and in many cases blood loss is also a contributory factor. Malignant disease of the kidneys, breast, prostate, thyroid, and lungs, in particular, may metastasize to bones, and in such an event "*myelophthistic*" anemia may develop. The picture then may be that of a pancytopenia (see p. 1325), or a leukemoid picture may result. The latter is marked by leukocytosis together with a moderate "shift to the left" in the leukocytic formula, and normocytic anemia. When a number of nucleated red corpuscles also appear in the peripheral blood, as they sometimes do, the term *leukoerythroblastic anemia* appropriately describes what is found. The pathogenesis of myelophthistic anemia was discussed briefly elsewhere (p. 207).

Endocrine insufficiency may be associated with anemia. Hypothyroidism is often accompanied by anemia of moderate degree. This is usually normocytic but can be macrocytic (p. 214). Slight or moderate anemia, usually normocytic, is found in Addison's disease and in pituitary insufficiency (Simmonds' disease).

As already described, the anemia of iron deficiency is hypochromic microcytic in type, and that due to lack of anti-pernicious-anemia principle and related substances is macrocytic. Protein deficiency is characterized by the presence of normocytic anemia. Deficiencies of the various B vitamins are rarely encountered in man in pure form. Multiple nutritional deficiencies are associated, as a rule, with only moderate anemia, usually normocytic in type.

BLOOD TRANSFUSION

Uses of Blood Transfusion. By far the most important and most frequent uses of whole blood transfusion are to restore blood volume after hemorrhage, trauma, or burns and to maintain the concentration of circulating hemoglobin at an adequate level in those types of anemia which cannot be relieved by specific measures such as liver or iron therapy.

The extent to which blood may be lost when hemorrhage occurs within a viscous or a muscle mass is frequently underestimated. Likewise it is not easy to judge the degree to which plasma has been depleted by leakage or how many red cells have been lost by hemolysis after a severe burn. Severe arterial hypotension following a traumatic injury or an event suggesting the possibility of a concealed hemorrhage, in the absence of evidence of other causes, is indicative of a blood volume deficit exceeding 30 per cent, i.e., 1,500 ml or more. When the blood volume deficit is 20 per cent or less, patients are unlikely to exhibit marked hypotension as long as they remain in the horizontal position. In general it may be said that it is more common to underestimate than to overestimate the amount of blood needed in the management of shock and to restore blood which has been lost.

Blood Substitutes. It should be emphasized that no substitute for whole blood has been found which is in any way comparable to the value of the red corpuscles and plasma. However, if whole blood is not available to restore blood volume, substitutes must be employed in emergencies. Of these, blood plasma is the best and in the dry form can be transported easily and kept ready at hand, but the danger of transmitting the virus of homologous serum hepatitis is so great that the use of pooled plasma cannot be recommended. Next in order of effectiveness is serum albumin, which has a physiologic effect closely approaching that of plasma. However, it is very expensive. For this and other reasons much attention has been given to the development of "plasma expanders," substances of such physicochemical properties that they will over-

come the disparity between the capacity of the circulatory system and the circulating blood volume that exists in shock. Of these the gelatins possess the fewest disadvantages, but dextran, a biosynthetic polysaccharide, has been found to be very effective and is being used more and more. It should be borne in mind that the plasma expanders should be employed only for the immediate emergency rather than repeatedly.

When shock is clearly not due to blood loss, transfusions are often withheld on the ground that such treatment is futile and may be dangerous. Nevertheless, where doubt exists concerning the nature of the shock, whether oligemic or nonoligemic, the administration of whole blood, plasma, or packed cells is justified and is not likely to be harmful. In nonoligemic shock pressor amines, such as norepinephrine, have been found useful, but such agents have been effective as interim therapy even in oligemic shock until whole blood could be obtained.

In the management of anemia other than that due to the acute loss of blood, blood transfusions are commonly used more generously than is necessary or desirable. The discovery of such anemia calls for careful study to determine its cause, rather than the blind administration of blood. Thus there is no justification for blood transfusion in iron-deficiency anemias or in the macrocytic anemias with megaloblastic bone marrow unless the anemia is extremely severe or unless surgical measures must be carried out at once. The patient who has such anemia has become adjusted to it, and the sudden change produced by transfusion is unnecessary. A physiologic response can be achieved by oral iron therapy or vitamin B₁₂ or folic acid administration, according to the nature of the deficiency. Again, in anemia associated with infection or in the management of the anemia of leukemia, Hodgkin's disease, or other disorders, the treatment of the underlying condition, whenever possible, is preferable to blood transfusion. Even in the management of aplastic anemia or other forms of anemia for which no specific therapy is available, it is better to give only enough transfusions to maintain the hemoglobin at a level consistent with reasonable activity rather than to attempt to maintain a normal level. Thereby the risk which each transfusion presents is reduced and the accumulation of iron in the tissues is less. Such patients are often maintained quite satisfactorily at hematocrit levels between 35 and 40 ml per 100 ml blood.

Whole blood, plasma, or albumin can be used to restore the colloid osmotic pressure of plasma to physiologic levels in cases of hypoproteinemia. Intravenous injections of salt-poor human serum albumin are particularly valuable in certain patients

with hepatic cirrhosis and ascites, the nephrotic syndrome, idiopathic hypoproteinemia, and the edema of malnutrition.

As a means for providing protein nutrients in patients restricted to parenteral feeding, other than as a temporary measure, intravenous injections of whole plasma or of serum albumin are impractical. This is because of their colloid osmotic activity and the consequent expansion of the recipient's plasma volume. Whole blood is even less valuable as a protein nutrient, in spite of its high protein content. This is not only because of the expansion of the patient's plasma volume thereby, but also because the contribution of the protein in the red corpuscles to the protein metabolic pool must await the natural destruction of the red corpuscles.

There is no sound basis for the use of transfusions in the management of the great majority of infections. It is true that blood transfusions have been employed effectively for the transfer of specific immune antibodies from convalescent donors to susceptible contacts where measles, mumps, and yellow fever have been present in epidemic form, and immune transfusions have been considered to be of value in treating certain infections, notably herpes ophthalmia and scarlet fever. However, other methods are now available for the management of most of these conditions.

Whole blood transfusions, plasma, or plasma fractions also can provide specific clotting factors which may be lacking in certain patients, such as antihemophilic globulin (fraction I), prothrombin, factors V (Ac-globulin) and VII (spca), and fibrinogen. Fresh normal plasma is capable of restoring all clotting factors and is particularly necessary for supplying factor V and the antihemophilic factor. Stored plasma can be depended on only for prothrombin, factor VII, factor IX (the plasma thromboplastin component, PTC), and fibrinogen. When equipment constructed entirely of plastic or coated material is used, fresh blood transfusions may also serve temporarily for the successful transfusion of blood platelets from one person to another. As a method of treating conditions where leukocytes are needed, this procedure is as yet neither practical nor very successful.

Finally, the removal of blood possessing pathogenic properties and its replacement with normal blood (exchange transfusion) is a valuable procedure in special circumstances as, for example, in certain cases of hemolytic disease of the newborn (erythroblastosis fetalis).

Although additional therapeutic benefits have been ascribed to blood transfusions, their value and therapeutic rationale remain unproved. Their use to "pep up" a patient who is not anemic and whose blood volume is normal is certainly unwarranted.

Risks Inherent in Blood Transfusion. The risk inherent in blood transfusion is not inconsiderable. In spite of the general knowledge of the danger of a hemolytic transfusion reaction resulting from mismatching of the major blood group antigens A, B, and D (Rh), and notwithstanding the care taken to avoid such errors, the incidence of hemolytic reactions to blood transfusions is substantial (Table 235-5). The mortality of hemolytic transfusion reactions is approximately 50 per cent. Furthermore, as discussed earlier (Chap. 47), there is a good chance of immunizing a recipient to one or more of the blood group antigens not tested for in the routine preparation for transfusion. It is noteworthy that the risk from sensitization is increased if a woman is transfused with blood from her husband or one of his relatives because of the possibility of her having been previously sensitized during pregnancy to a blood group substance foreign to her but inherent in the fetus. There is also the risk of erythroblastosis fetalis in subsequent pregnancies if sensitization occurs as a result of the transfusion.

In addition to hemolytic transfusion reactions, febrile or pyrogenic, anaphylactic, and infectious reactions may occur. Pyrogenic and urticarial reactions are usually mild and may be induced by small thrombi in the transfused blood, soluble toxic substances in new rubber tubing, improperly cleaned tubing, or insufficiently sterilized solutions which may contain small amounts of bacterial pyrogen. Of great seriousness are reactions due to the administration of blood heavily laden with dead or viable bacteria which have gained access to the blood by accident. Serum hepatitis is another serious and not completely avoidable complication of blood transfusion. There is also the possibility of transmission of malaria or of syphilis, but this can

Table 235-5. TRANSFUSION REACTIONS

Type	Cause	Incidence, %
Pyrogenic ..	Bacterial pyrogens	1.8-2.9
Febrile	Leukagglutinins	
Urticarial	Sensitivity (?)	0.8-1.1
Serum sickness ..	Unknown	Rare
Hemolytic ..	Mismatching of blood	0.1-0.3
Isosensitization ..	Repeated transfusions and in pregnancy	Not rare
Circulatory overload ..	Inductious augmentation of blood volume	Not rare
Infectious ..	Grossly contaminated blood	Rare
Transmission of disease	Hemolagous serum jaundice, syphilis, malaria	0.45-1.0
Air embolism	Entry of air into vein via tubing	Rare
"Cold reaction"	Cold agglutinins (?)	Not rare
Hypocalcemia	Exchange transfusions	Not rare
Hemorrhagic diathesis	Massive transfusions, etc.	Rare (?)
Fat embolism ..	Transfusion via bone marrow	Rare
Plasma sensitivity ..	Heat-labile plasma factor	In PNH

As already described, the anemia of iron deficiency is hypochromic microcytic in type, and that due to lack of anti-pernicious-anemia principle and related substances is macrocytic. Protein deficiency is characterized by the presence of normocytic anemia. Deficiencies of the various B vitamins are rarely encountered in man in pure form. Multiple nutritional deficiencies are associated, as a rule, with only moderate anemia, usually normocytic in type.

BLOOD TRANSFUSION

Uses of Blood Transfusion. By far the most important and most frequent uses of whole blood transfusion are to restore blood volume after hemorrhage, trauma, or burns and to maintain the concentration of circulating hemoglobin at an adequate level in those types of anemia which cannot be relieved by specific measures such as liver or iron therapy.

The extent to which blood may be lost when hemorrhage occurs within a viscus or a muscle mass is frequently underestimated. Likewise it is not easy to judge the degree to which plasma has been depleted by leakage or how many red cells have been lost by hemolysis after a severe burn. Severe arterial hypotension following a traumatic injury or an event suggesting the possibility of a concealed hemorrhage, in the absence of evidence of other causes, is indicative of a blood volume deficit exceeding 30 per cent, i.e., 1,500 ml or more. When the blood volume deficit is 20 per cent or less, patients are unlikely to exhibit marked hypotension as long as they remain in the horizontal position. In general it may be said that it is more common to underestimate than to overestimate the amount of blood needed in the management of shock and to restore blood which has been lost.

Blood Substitutes. It should be emphasized that no substitute for whole blood has been found which is in any way comparable to the value of the red corpuscles and plasma. However, if whole blood is not available to restore blood volume, substitutes must be employed in emergencies. Of these, blood plasma is the best and in the dry form can be transported easily and kept ready at hand, but the danger of transmitting the virus of homologous serum hepatitis is so great that the use of pooled plasma cannot be recommended. Next in order of effectiveness is serum albumin, which has a physiologic effect closely approaching that of plasma. However, it is very expensive. For this and other reasons much attention has been given to the development of "plasma expanders," substances of such physicochemical properties that they will over-

come the disparity between the capacity of the circulatory system and the circulating blood volume that exists in shock. Of these the gelatins possess the fewest disadvantages, but dextran, a biosynthetic polysaccharide, has been found to be very effective and is being used more and more. It should be borne in mind that the plasma expanders should be employed only for the immediate emergency rather than repeatedly.

When shock is clearly not due to blood loss, transfusions are often withheld on the ground that such treatment is futile and may be dangerous. Nevertheless, where doubt exists concerning the nature of the shock, whether oligemic or nonoligemic, the administration of whole blood, plasma, or packed cells is justified and is not likely to be harmful. In nonoligemic shock pressor amines, such as norepinephrine, have been found useful, but such agents have been effective as interim therapy even in oligemic shock until whole blood could be obtained.

In the management of anemia other than that due to the acute loss of blood, blood transfusions are commonly used more generously than is necessary or desirable. The discovery of such anemia calls for careful study to determine its cause, rather than the blind administration of blood. Thus there is no justification for blood transfusion in iron-deficiency anemias or in the macrocytic anemias with megaloblastic bone marrow unless the anemia is extremely severe or unless surgical measures must be carried out at once. The patient who has such anemia has become adjusted to it, and the sudden change produced by transfusion is unnecessary. A physiologic response can be achieved by oral iron therapy or vitamin B₁₂ or folic acid administration, according to the nature of the deficiency. Again, in anemia associated with infection or in the management of the anemia of leukemia, Hodgkin's disease, or other disorders, the treatment of the underlying condition, whenever possible, is preferable to blood transfusion. Even in the management of aplastic anemia or other forms of anemia for which no specific therapy is available, it is better to give only enough transfusions to maintain the hemoglobin at a level consistent with reasonable activity rather than to attempt to maintain a normal level. Thereby the risk which each transfusion presents is reduced and the accumulation of iron in the tissues is less. Such patients are often maintained quite satisfactorily at hematocrit levels between 35 and 40 ml per 100 ml blood.

Whole blood, plasma, or albumin can be used to restore the colloid osmotic pressure of plasma to physiologic levels in cases of hypoproteinemia. Intravenous injections of salt-poor human serum albumin are particularly valuable in certain patients

236 ERYTHREMIA (Polycythemia Rubra Vera)

M. M. Wintrobe

Definition. Erythremia, also known as Vaquez' or Osler's disease or splenomegalic polycythemia, is a disease of unknown etiology and of insidious onset and slow, chronic course. It is characterized by a striking absolute increase in the quantity of circulating red corpuscles and, often, by evidence of increased production of myeloid leukocytes and even of platelets. Splenomegaly and a red "cyanosis" of the skin, as well as increase in the viscosity of the blood and in the total volume of the blood, are additional features of this disorder.

History. Vaquez in 1892 described a case of polycythemia which he had originally attributed to congenital heart disease. Osler gave a more complete description in 1903.

Etiology and Pathogenesis. The term *polycythemia* signifies an increase above the normal in the number of red corpuscles in the circulating blood. This increase usually, though not always, is accompanied by a corresponding increase in the quantity of hemoglobin and in the volume of packed red corpuscles. The increase may or may not be associated with an increase in the total quantity of red cells in the body. It is important to distinguish between *absolute* polycythemia (an increase in the total red corpuscle mass) and *relative* polycythemia, which occurs when, through loss of blood plasma, the concentration of the red corpuscles becomes greater than normal in the circulating blood. This may be the consequence of abnormally lowered fluid intake or of marked loss of body fluids, such as occurs in persistent vomiting, severe diarrhea, copious sweating, or acidosis (Chaps. 13, 50). Loss of electrolyte from the extracellular compartment, when not accompanied by corresponding loss of water, leads to a decline of osmolar concentration in the extracellular fluid. The resulting shift of water into the tissue cells may produce relative polycythemia, sometimes of high grade. In certain types of peripheral circulatory failure there is a loss of plasma into the interstitial fluid. Such a shift takes place largely in the periphery, with the result that the polycythemia may be more marked in capillary blood than in that from central blood vessels.

Because the term *polycythemia* is loosely used to refer to all varieties of increase in the number of red corpuscles, the terms *erythrocytosis* and *erythremia* are preferred in referring to two forms of absolute polycythemia. *Erythrocytosis* denotes absolute polycythemia which occurs in response to some known stimulus; *erythremia* refers to the dis-

usually be avoided by appropriate inquiry and examination of the donor.

Before subjecting a patient to blood transfusion, thought should be given to his cardiovascular status. In all persons with impaired cardiac function the administration of whole blood or other osmotically active solutions must be made cautiously and slowly, since an increase in venous pressure and pulmonary edema is easily produced. Particular care should be used in regard to concentrated serum albumin because of its capacity to withdraw fluid from the tissues into the circulation. Such patients, furthermore, should be propped in a sitting position during the transfusion. The so-called "speed reaction" is the result of circulatory overloading, and its manifestations are those of right-sided heart failure. It is produced by overrapid infusion in relation to the cardiovascular reserve of the patient and can be prevented by slow administration of blood. If the purpose of transfusion is to raise the concentration of circulating hemoglobin rather than to increase the total blood volume, red cell suspensions are as effective as are whole blood transfusions and offer the advantage that the volume of injected material is relatively small. When it is not convenient to prepare red cell suspensions, 60 to 80 per cent of the plasma can be withdrawn from the blood after spontaneous or mechanical sedimentation of the red cells, thereby reducing the volume of injected material as well as its salt content.

Patients who have received many transfusions may develop cold agglutinins and may react with a chill if blood is given without being warmed. Sometimes allowing the blood to stand at room temperature is adequate, but in many instances it is necessary to have some of the transfusion tubing rest in a water bath maintained at body temperature, thus allowing the blood to be warmed before it enters the patient's vein. Other complications which may develop in those subjected to repeated transfusions are febrile reactions due to leukoagglutinins and, especially in paroxysmal nocturnal hemoglobinuria, sensitivity to a heat-labile constituent of fresh normal plasma. In such patients only well-washed red cells can be used in transfusion.

Except in emergency, it is always wise to give the first 50 ml of blood slowly and under the scrutiny of a doctor or nurse. In addition it is well, whenever possible, to wait 30 min in order to determine whether a reaction will occur. Fatal transfusion reactions have occurred only when more than 300 ml of blood has been given. It is unwise to use blood for transfusion which has been brought to room temperature, cooled, and then rewarmed, since the likelihood of an infectious reaction is thereby increased.

Universal Donor. While the use of group O blood

(universal donor) for general transfusion purposes is undesirable, in certain types of hospitals which use transfusion therapy almost exclusively on an emergency basis, the practice is followed. In such situations the two chief hazards should be kept in mind. One is the danger of mistyping A₂ donors as group O, an error which can be eliminated by serum or "back typing." The second danger, that of the group O person whose serum contains high titers of anti-A and anti-B or both, is met in part by attempting to discover and screen out such donors, and in part by adding A and B substances to the group O blood.

236 ERYTHREMIA (Polycythemia Rubra Vera)

M. M. Wintrobe

Definition. Erythremia, also known as Vaquez' or Osler's disease or splenomegalic polycythemia, is a disease of unknown etiology and of insidious onset and slow, chronic course. It is characterized by a striking absolute increase in the quantity of circulating red corpuscles and, often, by evidence of increased production of myeloid leukocytes and even of platelets. Splenomegaly and a red "cyanosis" of the skin, as well as increase in the viscosity of the blood and in the total volume of the blood, are additional features of this disorder.

History. Vaquez in 1892 described a case of polycythemia which he had originally attributed to congenital heart disease. Osler gave a more complete description in 1903.

Etiology and Pathogenesis. The term *polycythemia* signifies an increase above the normal in the number of red corpuscles in the circulating blood. This increase usually, though not always, is accompanied by a corresponding increase in the quantity of hemoglobin and in the volume of packed red corpuscles. The increase may or may not be associated with an increase in the total quantity of red cells in the body. It is important to distinguish between *absolute* polycythemia (an increase in the total red corpuscle mass) and *relative* polycythemia, which occurs when, through loss of blood plasma, the concentration of the red corpuscles becomes greater than normal in the circulating blood. This may be the consequence of abnormally lowered fluid intake or of marked loss of body fluids, such as occurs in persistent vomiting, severe diarrhea, copious sweating, or acidosis (Chaps. 13, 50). Loss of electrolyte from the extracellular compartment, when not accompanied by corresponding loss of water, leads to a decline of osmolar concentration in the extracellular fluid. The resulting shift of water into the tissue cells may produce relative polycythemia, sometimes of high grade. In certain types of peripheral circulatory failure there is a loss of plasma into the interstitial fluid. Such a shift takes place largely in the periphery, with the result that the polycythemia may be more marked in capillary blood than in that from central blood vessels.

Because the term *polycythemia* is loosely used to refer to all varieties of increase in the number of red corpuscles, the terms *erythrocytosis* and *erythremia* are preferred in referring to two forms of absolute polycythemia. *Erythrocytosis* denotes absolute polycythemia which occurs in response to some known stimulus; *erythremia* refers to the dis-

case of unknown etiology which is the main subject of this chapter.

Erythrocytosis develops as a consequence of a variety of factors and represents a physiologic response to conditions of hypoxia. Sojourn at high altitudes leads to defective saturation of arterial blood with oxygen and stimulates the production of more red corpuscles. Immediately on ascent to a high altitude, symptoms such as fatigue, dizziness, headache, nausea, vomiting, ringing in the ears, and prostration may appear. In most persons adaptation soon occurs, with the development of polycythemia and other compensatory adjustments. However, a disorder may set in insidiously a few years later, or even as long as 20 years after continued residence at high altitudes, leading to the development of a condition known as *chronic mountain sickness* or *seroche* (Monge's disease).

Emphysema is the most common of the chronic pulmonary conditions which may lead to erythrocytosis. Silicosis, with extensive pulmonary fibrosis, is another. Pulmonary arteriovenous fistula may lead to impaired saturation of arterial blood with oxygen, with the consequent development of erythrocytosis and of a clinical picture resembling closely that of certain types of congenital heart disease. Cavemous hemangioma of the lung may be associated with polycythemia. Hypertension of the lesser circulation, with pulmonary arterial and arteriolar sclerosis, may be accompanied by a train of symptoms such as asthma, bronchitis, dyspnea, and cyanosis, as well as erythrocytosis—a syndrome known as *Ayerza's syndrome*, or *cardiaco negro*.

Under the mechanical conditions existing in obese patients, periods of shallow breathing may develop and result in alveolar hypoventilation and erythrocytosis. The fat, somnolent, red-faced boy of Dickens' "The Pickwick Papers" may well have been an example of this disorder. The claim that abnormal function of the respiratory center may be the cause of hypoxemia and absolute polycythemia requires substantiation.

The partial shunting of blood from the pulmonary circuit, such as occurs in congenital heart disease, is the cause of the most striking erythrocytosis resulting from abnormality in the circulation. Erythrocyte counts as high as 13 million, which are possible only when the red corpuscles are smaller than normal, have been observed in such cases, with volumes of packed red cells even as high as 86 ml per 100 ml of blood. The most common defects producing such polycythemia are pulmonary stenosis, usually with defective ventricular or auricular septum, patent foramen ovale, or patent ductus arteriosus; complete transposition of arterial trunks; and tetralogy of Fallot. Erythrocytosis does not usually occur in patients with acquired heart disease

but occasionally is seen in persons with mitral stenosis.

The excessive use of coal-tar derivatives and other forms of chronic poisoning, by producing abnormal hemoglobin pigments such as methemoglobin and sulfhemoglobin (Chap. 237), may cause erythrocytosis. Another chemical agent, cobalt, has produced erythrocytosis in experimental animals but the mechanism is obscure.

Erythrocytosis is found in Cushing's syndrome and can be produced by the administration of large amounts of adrenocorticosteroids. In many ways most curious of all are the instances of polycythemia observed in association with various tumors. These have been chiefly of two varieties, infratentorial and renal. The tumors in the posterior fossa of the skull have usually been vascular, and their removal has frequently been associated with a return to normal hemoglobin levels. This response has also been noted in many of the cases of hypernephroma, polycystic disease of the kidneys, and hydronephrosis which were accompanied by polycythemia. The frequency of the association of polycythemia with the above-mentioned renal disorders has ranged from 0.3 to 2.6 per cent of cases in different series.

The term *stress erythrocytosis* has been applied to the polycythemia seen occasionally in very active, hard-working persons in a state of anxiety, who appear florid but who have none of the characteristic signs of erythremia—no splenomegaly or marked leukocytosis with immature cells in the blood. In such individuals the total red cell mass is normal and the plasma volume is below normal.

In essence, then, erythrocytosis is known to develop when there is

1. Defective saturation of arterial blood with oxygen, resulting from (a) decreased atmospheric pressure, and (b) impaired pulmonary ventilation

2. Abnormality in circulation, due to (a) shunting (congenital heart disease), and possibly (b) diminished blood supply to the bone marrow (in certain patients with chronic cardiac disease)

3. Defect in circulating blood pigment

It is clear, however, that in addition to these long-recognized mechanisms, some instances of erythrocytosis cannot be explained on these grounds.

4. The adrenocortical secretions may produce polycythemia

5. Humoral mechanisms of less well-defined nature may play a role. Considerable evidence supports the view that a humoral factor, "erythropoietin," plays a significant role in erythropoiesis and also indicates that this factor may arise in the kidneys. In fact, even the effect of anoxia on the bone marrow may not be direct but may be medi-

ated by a humoral mechanism. Thus, in a case of patent ductus arteriosus occurring distal to the origin of the subclavian artery, it was shown that the sternal marrow manifested the same pronounced normoblastic hyperplasia as the iliac marrow even though the oxygen saturation of the latter was markedly decreased as compared with the normal saturation of the sternal marrow.

In the disease *erythremia*, however, the above mechanisms have not been found to be involved. The most common form of erythremia appears in middle or late life, it is often accompanied by splenomegaly, and often the increase in number of red corpuscles is but a part of a generalized myeloid hyperplasia which may be manifested in elevated leukocyte counts and an increase in the number of platelets. A close relationship to chronic myelocytic leukemia is suggested by such cases.

Polycythemia of unknown cause has also been seen in children, in rare instances, and occasionally appears as a familial disorder. Such cases may well be unrelated to the classical disorder described by Vaquez and Osler.

Pathology. The striking changes are those related to the increase in total blood volume. All the organs are engorged with blood, the veins stand out like "bunches of thick worms," and there may be thromboses or anemic infarcts. The *bone marrow* is dark red in color and very cellular. Microscopically, this is found in most instances to be due to hyperplasia of all the marrow elements. In some cases the percentage of normoblasts is increased, in others the proportions of myelocytes and myeloblasts or of basophilic and eosinophilic cells may be greater than normal.

The spleen is enlarged, chiefly from hyperplasia of the pulp and distention with blood. Infarcts are common. There may be foci of extramedullary blood formation in the spleen, the liver, and occasionally elsewhere as well. Cirrhosis of the liver has been observed in a number of instances.

Symptomatology. The onset is insidious and the progress gradual. Headache, dizziness, ringing in the ears, or visual disturbances; dyspnea, lassitude, or weakness; skin or mucous membrane hemorrhages; a sense of weight in the abdomen due to the enlargement of the spleen; or irritability, depression, forgetfulness, or vague symptoms suggesting neurasthenia are complaints encountered in many cases. Various gastrointestinal symptoms such as fullness, belching, or constipation may be present, or symptoms of peptic ulcer may be found. Sometimes the symptoms are those attributable to increased metabolism: lassitude, increased sweating, and loss of weight. Swelling and pain in the extremities may be very troublesome. In still other cases the symptoms are so insignificant that the polycythemia is discovered only accidentally.

The face is a deep red rather than truly cyanotic. The color is most noticeable in the lips, cheeks, tip of the nose, ears, and neck. The distal portions of the extremities may be more truly cyanotic, since the highly viscous blood circulates more sluggishly there than is normal. Ecchymoses are common, and epistaxis and bleeding of the gums are frequently encountered. Cardiac abnormality is unusual, but vascular disturbances are common. These include venous thromboses, coronary thrombosis, and cerebrovascular accidents. The blood pressure is more often normal than elevated. Enlargement of the liver is frequent, and splenomegaly is found in at least 75 per cent of cases. The spleen may be just palpable or it may extend even to the pelvic brim.

Blood. Erythrocyte counts of 7 to 10 million cells per cu mm are common. Unless hemorrhage has occurred or venesections have been performed, there is a corresponding increase in hemoglobin and in volume of packed red corpuscles. The individual red corpuscles appear normal, although occasional polychromatophilia or basophilic stippling may be noted. The finding of nucleated red corpuscles and the appearance of small numbers of myelocytes and even earlier forms in the blood give a clue to the hyperplastic state of the bone marrow, leukocytosis, sometimes of marked degree (60,000 per cu mm), due to an increase of the granulocytes, and high platelet counts, when present, give further evidence of overactivity. The percentage of reticulocytes is not increased unless there has been recent bleeding. The osmotic fragility of the red corpuscles is not significantly altered. There may be some evidence of increased blood destruction, in the form of slight bilirubinemia and increased excretion of urobilinogen. The viscosity of the blood is greatly increased, even five- to tenfold. The thick, sticky blood may be slow to coagulate and the clot may not retract. Bleeding and clotting times are usually normal, however.

The total blood volume is substantially increased (150 to 300 per cent of normal), entirely because of an increase in red corpuscle mass.

Other Laboratory Findings. These include increased basal metabolic rate in many cases; normal, increased, or reduced gastric secretion, even achlorhydria; occasionally, increased serum uric acid level and, sometimes, increased endogenous uric acid excretion; and normal urine or slight proteinuria.

Diagnosis. The symptoms of erythremia alone may suggest a variety of disorders, but once the blood has been examined, the problem is to differentiate secondary forms of polycythemia (erythrocytosis) from the "primary" disorder. Failure to discover a cause for the polycythemia, and the presence of a reddish rather than bluish cyanosis favor the diagnosis of erythremia. Splenomegaly is

very unusual in erythrocytosis, even when the erythrocyte count is very much increased. What is more, in the latter condition, leukocytosis, immature leukocytes, and an increase in the platelet count are hardly ever found and normoblasts are much more uncommon in the blood than in erythremia.

An absolute increase in red corpuscle mass is found in erythrocytosis as well as in erythremia. Measurement of blood volume, therefore, does not aid in differentiating "secondary" polycythemia, but because of variations in plasma volume it is a truer index of the degree of polycythemia than the hematocrit level. It is also helpful in the occasional patient, often a heavily built, middle-aged, and sometimes hypertensive male, in whom there is only relative polycythemia ("stress erythrocytosis"). Measurement of arterial oxygen saturation is useful in differentiating erythrocytosis due to cardiac or pulmonary disease, for in the latter, oxygen saturation is reduced more or less in inverse proportion to the degree of polycythemia, whereas in erythremia it is normal or nearly normal.

Course and Complications. Barring the development of serious complications, the course of erythremia, adequately treated, is chronic and the disorder is often compatible with many years of life. The most dangerous complications are vascular: thrombosis or hemorrhage. Therapy, by keeping the red corpuscle mass at a nearly normal level, can effectively reduce blood viscosity and thus serves to reduce the likelihood of such vascular accidents. Intercurrent infections, especially of the respiratory tract, may be troublesome, and bronchitis and emphysema may develop. Peptic ulcer and hypertension are frequent complications; less often, gout and cirrhosis of the liver occur. The development of typical chronic myelocytic leukemia in a number of cases of erythremia has given support to the view that there may be a close relationship between these two disorders.

Treatment. Treatment is symptomatic, since the cause of erythremia is unknown. Symptomatic relief is best achieved by reducing the red corpuscle mass to something approaching normal. This is most quickly achieved by *venesection*. Approximately a pint of blood is removed twice a week or even more often, until the volume of packed red corpuscles approaches normal. Then the procedure may need to be repeated only once a month or less often. *Phenylhydrazine hydrochloride*, though now rarely used, is effective in destroying the red corpuscles, but it is best first to use *venesection* to lower the blood level to normal, subsequently giving only enough of the hemolytic agent to maintain the blood at normal. For this purpose 0.1 Gm. in capsules, once a day, every other day, or every third day should be adequate. The use of such small doses will avoid complications of phenylhydrazine

therapy such as thrombosis and acute hemolytic anemia. This drug should not be used for bedridden patients or for those who have thrombosis already.

Instead of removing or destroying the excessive red corpuscles, hematopoiesis may be inhibited by irradiation or by chemotherapy. The effects of irradiation are slow to appear, however, and consequently *venesection* must be used at the same time initially. The intravenous injection of radioactive phosphorus (P^{32}) is more satisfactory than roentgen therapy. The procedure depends on the fact that the radioactive phosphorus passes to tissues which have a high phosphorus content. The concentration of P^{32} in the bones places this agent in a strategic position. Usually 3 to 5 millicuries of P^{32} is given. After 10 to 12 weeks, if symptomatic and hematologic improvement are inadequate, a second dose is administered. Subsequent therapy is "titrated" according to need, but intervals between injections should not be shorter than 10 weeks, and leukocyte and platelet counts should be included in the blood examinations as guides in avoiding marrow aplasia from overdosage. Remissions of 6 to 10 months are common, but much longer ones are not unusual.

Although agents such as triethylenemelamine and busulfan have been shown to be effective in the treatment of erythremia, they offer no advantages over radioactive phosphorus.

237 METHHEMOGLOBINEMIA, SULFHEMOGLOBINEMIA

George E. Cartwright

METHHEMOGLOBINEMIA

Methemoglobin is an oxidation product of hemoglobin in which the iron is in the ferric state. Methemoglobin cannot bind oxygen or carbon di-

oxide. Within the erythrocyte, about 99 per cent of the hemoglobin is in the reduced state (HbFe^{++}) and 1 per cent is in the oxidized state (HbFe^{3+}). Under normal circumstances these two forms of hemoglobin are in equilibrium.

The system in the red cell for reduction of methemoglobin employs reduced diphosphopyridine nucleotide (DPNH), formed from the oxidation of glucose, as the electron donor. Reduced DPN does not react directly with methemoglobin. The enzyme, DPN diaphorase, is required for the reduction. This was originally referred to as the "methemoglobin reductase a" system.

Etiology. Methemoglobinemia may be either inherited or acquired. Two distinct types of hereditary methemoglobinemia have been described. A number of cases of hereditary methemoglobinemia have been observed in Greece but have not yet been classified as to the type of biochemical abnormality.

Hereditary methemoglobinemia due to a deficiency of the enzyme DPN diaphorase has been described in Alaskan Eskimos and Athabaskan Indians. The disease is transmitted as an autosomal recessive trait. Individuals heterozygous for the trait have about half the normal level of the diaphorase enzyme and are asymptomatic; 93 to 99 per cent of the hemoglobin is in the reduced state. Individuals homozygous for the trait have a complete lack of the erythrocyte enzyme and are cyanotic from birth; 5 to 60 per cent of the hemoglobin is present as methemoglobin. The rate at which methemoglobin is reduced is greatly impaired. The disease has been described in infants and children. The failure to observe the disease state in adults suggests that the disease is associated with early mortality or that this form of methemoglobinemia disappears with age.

Hereditary methemoglobinemia associated with an abnormal hemoglobin (hemoglobin M) has been described in families of German, Greek, Swiss, and Italian descent. The disease is transmitted as a non-sex-linked dominant trait. The fundamental defect exists in the structure of the globin. The formation of methemoglobin is due to increased sensitivity of hemoglobin M to oxidation and not to a slow rate of methemoglobin reduction. On the basis of absorption spectra at least three different M hemoglobins have been described. These have been designated hemoglobins M_B , M_S , and M_H after the cities (Boston, Saskatoon, and Milwaukee) where they were described. Cyanosis is the only clinical manifestation described. Cyanosis is usu-

ally absent at birth and first appears 6 weeks to 6 months after birth. Hemoglobin M, unlike most of the other hemoglobinopathies, is not associated with hemolytic anemia.

A number of patients with congenital methemoglobinemia have been reported without a familial history of the disease, and a few patients with *idiopathic methemoglobinemia* have been observed in whom the congenital nature of the disease was not clearly demonstrated.

Acquired (secondary) methemoglobinemia is more common than hereditary methemoglobinemia and is caused by contact with drugs containing amino or nitro groups (Table 237-1). These drugs preferentially oxidize hemoglobin and, in sufficient amounts, overcome the normal reducing mechanism of the erythrocytes. When exposure to the offending drug ceases, the methemoglobin is rapidly converted to the reduced compound and the cyanosis disappears. Nitrates after ingestion may be converted to nitrites by intestinal bacteria, and after absorption from the intestine produce methemoglobin. Cases of methemoglobinemia due to nitrates or nitrites have been reported following the use of bismuth subnitrates or of ammonia or potassium nitrate, from the therapeutic use of amyl nitrite or nitroglycerin, from food high in nitrates, in infants drinking well water high in nitrates, from the inhalation of nitrous gases by arc welders, and from the ingestion of coloring syrup. Aniline dyes may produce methemoglobinemia by penetration of the intact skin. Contact with dyed blankets, laundry marks on diapers, and freshly dyed shoes have produced methemoglobinemia. The ingestion by children of certain red wax crayons containing p-nitroaniline has resulted in methemoglobinemia. The commonly dispensed analgesic and antipyretic drugs, acetanilid and phenacetin, are aniline derivatives and have frequently been found responsible for methemoglobinemia. Certain sulfonamides, such as sulfanilamide, Prontosil, sulfathiazole, and sulfapyridine, but not sulfadiazine or sulfamerazine, produce the condition.

Enterogenous cyanosis is a term used to refer to a clinical syndrome characterized by attacks of cyanosis, headache, abdominal pain with either diarrhea or constipation, dyspnea, dizziness, collapse, and syncope. Many of the patients reported were taking aniline derivatives for headache. It has been suggested that because of the gastrointestinal disease there was an abnormal production and absorption of nitrites. Sulfhemoglobinemia has been present frequently, together with methemoglobinemia, in the blood of these patients.

In addition to the above types of methemoglobinemia, rare cases of acquired hemolytic anemia with paroxysmal methemoglobinemia have been reported.

Clinical Manifestations. When as little as 1.5 Gm of methemoglobin is present in 100 ml of blood, recognizable cyanosis results. In contrast, about 5 Gm of reduced hemoglobin must be present before a comparable degree of cyanosis occurs. Since methemoglobin is incapable of combining with oxygen, the symptoms of methemoglobinemia are attributable to the hypoxia produced by the lowered oxygen capacity of the blood. The severity of the symptoms is related to the quantity of methemoglobin present, the rapidity with which the methemoglobinemia develops, and the capacity of the individual's cardiorespiratory and hematopoietic systems to adjust to the hypoxia. In general, levels of less than 20 per cent methemoglobin are usually not associated with symptoms. At levels of 20 to 50 per cent, fatigue, weakness, dyspnea, tachycardia, headaches, and dizziness may occur. Only rarely is enough methemoglobin present to cause coma and death.

Diagnosis. Methemoglobinemia should be suspected in any patient with intense cyanosis, especially if physical examination fails to reveal evidences of cardiovascular or pulmonary disease and if the cyanosis is unrelieved by oxygen therapy. If blood withdrawn from a vein shows the characteristic chocolate-brown coloration, the diagnosis of an abnormal blood pigment is almost certain. If the pigment is not in the plasma but in the erythrocytes, and if the chocolate-brown color remains after shaking the blood in air for 15 min, there is additional presumptive evidence for the presence of either methemoglobinemia or sulfhemoglobinemia.

A family history of cyanosis helps to delineate the hereditary forms of the disease. A negative family history of cyanosis and a recent history of drug ingestion (Table 237-1) suggest the acquired form of the disease. The hereditary form of the disease, which is due to a deficiency of the diaphorase enzyme, can be recognized with certainty only by determination of erythrocyte diaphorase activity. The diagnosis of the hemoglobin M disorders can be established by starch block electrophoresis (pH 7.0 to 7.2) of hemolysates and by a spectrophotometric absorption analysis of the patient's hemoglobin.

Methemoglobin (other than M hemoglobins) may be differentiated from sulfhemoglobin by examining a 1:10 or 1:100 aqueous dilution of blood in a hand spectroscopic. The absorption band of methemoglobin (830 m μ) may be confused with that of sulfhemoglobin (618 m μ), but on the addition of 2 or 3 drops of 5 per cent potassium cyanide the band due to methemoglobin disappears, whereas the sulfhemoglobin band is unchanged. The addition of hydrogen peroxide causes dissolution of the sulfhemoglobin band, but not of the methemoglobin band.

Table 237-1. AMINO AND NITRO COMPOUNDS PRODUCING METHHEMOGLOBINEMIA

<i>Aromatic drugs</i>	<i>Aliphatic and inorganic drugs</i>
Aniline	Sodium nitrite
Anilinoethanol	Hydroxylamine
Phenacetin	Dimethylamine
Acetanilid	Nitroglycerin
Methylacetanilide	Amyl nitrate
Hydroxylacetanilide	Ethyl nitrite
Prontosil	Bismuth subnitrate
Sulfanilamide	Ammonium nitrate
Sulfathiazole	Potassium nitrate
Sulfapyridine	
Phenylenediamine	
Aminophenol	
Toluenediamine	
Alpha-naphthylamine	
Para-aminopropiophenone	
Phenylhydroxylamine	
Tolylhydroxylamine	
Nitrobenzene	
Dinitrobenzene	
Trinitrotoluene	
Nitrosobenzene	
Para-nitroaniline

Treatment. In patients with hereditary methemoglobinemia due to deficiency of DPN diaphorase, the reducing agent ascorbic acid may be given daily by mouth in an amount of 100 to 500 mg. Methylene blue accelerates the reduction of methemoglobin and is effective in a daily dose of 100 to 300 mg by mouth.

Ascorbic acid and methylene blue are of little or no value in alleviating the cyanosis due to hemoglobin M.

In patients with mild drug-induced methemoglobinemia no therapy is necessary other than removal of the offending agent, since reduction of the methemoglobin occurs rapidly as a result of the intact normal reconversion mechanism. In those patients in whom therapy is necessary, methylene blue, 1 to 2 mg per kg body weight given intravenously over a 5-min period in a 1 per cent solution, is the agent of choice. If cyanosis has not disappeared within an hour, a second dose of 2 mg per kg body weight should be given. Dosages should not exceed 7 mg per kg since toxic effects such as dyspnea, precordial pain, restlessness, apprehension, a sense of oppression, and fibrillar tremors may occur.

SULFHEMOGLOBINEMIA

Sulfhemoglobin is a sulfur-containing hemoglobin derivative. The exact mode of linkage of the sulfur

to the hemoglobin is unknown. Sulfhemoglobin is not found in erythrocytes under normal circumstances. Once it has been formed it is not reversible to hemoglobin, the abnormal derivative remaining in the erythrocytes until they are destroyed.

Sulfhemoglobinemia may result when one of the oxidizing drugs listed in Table 237-1 has been taken.

Phenacetin (A.P.C., Empirin Compound, Anacin, Stanback) and acetanilid (Bromoseltzer) are the drugs found most frequently to be the causative agents. Constipation is present in at least half the patients, and it has been suggested, without documentary proof, that this contributes to the development of the condition by enhancing the production of hydrogen sulfide in the bowel.

Sulfhemoglobin is inert as an oxygen carrier, and when it is present intense cyanosis results. Somewhat less than 0.5 Gm sulfhemoglobin per 100 ml blood causes a degree of cyanosis equal to that of 1.5 Gm methemoglobin or 5 Gm reduced hemoglobin. Although the concentration of sulfhemoglobin may be found to be as high as 10 Gm per 100 ml, the life of the patient is not endangered and symptoms which can be attributed to the sulfhemoglobinemia are rarely present. Since many of the patients in whom sulfhemoglobinemia develops are neurotic or are taking drugs for a chronic headache or constipation, the symptoms which can be elicited are probably not attributable to the sulfhemoglobinemia. Symptoms of bromide intoxication frequently complicate the clinical picture in those ingesting Bromoseltzer. Once formed, there is no way of removing the sulfhemoglobin except by phlebotomy. In time the affected red corpuscles wear out and are destroyed. Treatment requires interdiction of the offending drug and correction of the intestinal conditions causing the disorder.

Enterogenous sulfhemoglobinemia is a term used to refer to the syndrome of sulfhemoglobinemia, cyanosis, and constipation or other evidence of disturbed bowel function without the history of the ingestion of an oxidizing or sulfur-containing drug. Rare cases of acquired hemolytic anemia with paroxysmal sulfhemoglobinemia and methemoglobinemia have been reported.

238 THE PURPURAS

M. M. Wintrobe

Definition. The term *purpura* refers to extravasations of blood into the skin or mucous membranes. They may vary from the size of a pin point or slightly bigger (petechiae) to much larger areas (ecchymoses). Purpura is but one manifestation of abnormal bleeding, already discussed (p. 217).

THROMBOCYTOPENIC PURPURA

Definition. This term refers to purpura which is accompanied by a significant reduction in the platelet count. There is at the same time prolongation of bleeding time, a positive tourniquet test result, and poor clot retraction, but the coagulation time and prothrombin time are normal. The purpura may be *idiopathic*, this also being known as *purpura hemorrhagica* or *Weilhof's disease*; or it may be *symptomatic*: the effect of various chemical, vegetable, animal, or physical agents, the accompaniment of certain infections, or a part of the picture of various blood disorders.

History. Weilhof, in 1735, distinguished purpura hemorrhagica as an entity distinct from the purpuric manifestations of various pestilential fevers and differing from other hemorrhagic disorders. Denys noted the thrombocytopenia in 1887, while Kaznelson proposed treatment by splenectomy in 1916.

Etiology and Pathogenesis. Purpura hemorrhagica occurs most frequently in children and in young adults, and is somewhat more common in the female than in males. No more than 10 per cent of cases begin after the age of forty. Not infrequently there is a family history of excessive bleeding. The condition is rare in Negroes.

In the bone marrow the number of megakaryocytes is normal or may even be increased. However, in contrast to the normal picture, few or no platelets are found about their margins. It is also significant that splenectomy is often followed by striking improvement. These observations have led to the assumption that this disorder is caused by

(1) a decreased rate of formation of platelets from megakaryocytes as the consequence of splenic inhibition, (2) platelet destruction by the spleen, or (3) a combination of damage to both megakaryocytes and circulating platelets, perhaps through the action of a humoral factor in the plasma. That the last is true in many cases, probably as the result of an immunologic mechanism, is indicated by studies in which platelet agglutinins were shown to be present in the plasma of patients with essential thrombocytopenic purpura. It was also demonstrated that the injection of plasma from patients with this disease into normal recipients was associated with thrombocytopenia, bleeding phenomena, and alterations in the megakaryocytes. Furthermore, transfused platelets disappear with extraordinary rapidity from the circulation of patients with acute idiopathic thrombocytopenic purpura. It is plausible to assume that the spleen removes sensitized platelets and may also produce some of the platelet agglutinin.

Platelet agglutinins were first described in patients with thrombocytopenic purpura due to Sedormid. In these cases it was shown that the drug forms an antigenic complex with the platelets, to which an antibody is formed. It is possible that in "idiopathic" thrombocytopenic purpura an unidentified toxin affects both platelets and capillary endothelium, which are antigenically similar, and that an antibody to these damaged tissues is produced.

That there is, in addition to thrombocytopenia, a defect in the capillary endothelium is suggested by the fact that hemorrhage in this disease is not always closely correlated to the degree of platelet reduction. It has been proposed that the capillaries are unusually permeable or that they are incapable of adequate contraction. For the latter hypothesis, evidence has been presented which is based on direct observation.

The prolonged bleeding time is explained by a failure of the capillaries to retract as well as by the lack of sufficient platelets to plug the opening of a bleeding vessel. The intracutaneous oozing of blood when capillary pressure is increased (tourniquet test) is explained in the same way. Coagulation time is normal because few platelets are needed to initiate clotting. The clot, however, is loose and retracts poorly because a large number of platelets are needed for syneresis.

There is much to suggest that idiopathic thrombocytopenic purpura is a syndrome which may arise in a number of different ways. Although an immunologic mechanism is probably important in many cases, it seems likely that in other instances the underlying cause may be splenic dysfunction which leads to suppression of platelet formation, or metabolic aberrations leading to deficiency of factors necessary for platelet production, or still other

mechanisms or etiologic factors as yet unrecognized.

Symptomatology. Purpura hemorrhagica may begin abruptly and disappear spontaneously just as suddenly; or its manifestations may seem to have been present a long time, occasionally so long that they might appear to be characteristic of the individual concerned. The bleeding may be mild with perhaps only inconspicuous purpuric spots in the skin; or it may be severe and not only may lead to serious loss of blood but also may occur into vital areas such as the cranium or the diaphragm. All variations between these extremes may be encountered, and the disorder may wax and wane in intensity. Acute and chronic forms of the disorder have been described, and by some investigators are regarded as different entities. It is not unusual for symptoms first to become apparent following an acute infection.

The lesions in the skin usually consist of minute, red hemorrhages which differ from telangiectases in that they do not blanch on pressure. Often ecchymoses are found as well. Mucous membrane hemorrhages are common, bleeding from the nose, mouth, or uterus being particularly frequent and sometimes severe. Not rare are instances in which menorrhagia is the chief complaint, and this often is the only prominent clinical sign other than the abnormalities in the blood. Bleeding, however, may occur into any tissue and from any orifice. Frequently, also, excessive bleeding may be noted following tooth extraction, tonsillectomy, operations, or injuries.

Fever of mild degree may be present in acute cases. The spleen may extend a fingerbreadth below the costal margin. There is no general glandular enlargement, sternal tenderness, or other physical sign other than those attributable to hemorrhage or anemia.

Blood and Bone Marrow Findings. These have, in the main, been mentioned already. What platelets may be seen in the blood smear are often unusual in appearance: giant or minute forms, or deeply stained ones. The bleeding time may be slightly, moderately, or greatly prolonged (8 to 60 min or more). Anemia, if present, is proportional to the amount of blood lost. If there has been much bleeding, signs of stimulated erythropoiesis will be found: reticulocytosis, polychromatophilia, even occasional normoblasts. The leukocyte count may be normal, but if acute blood loss has taken place there may be a moderate leukocytosis with slight "shift to the left." In some chronic cases lymphocytosis has been observed.

Diagnosis. Hemorrhage not due to obvious cause, if associated with thrombocytopenia, prolonged bleeding time, poor clot retraction, and positive tourniquet test can be attributed to thrombocytopenic purpura. Prolonged bleeding time is charac-

teristic of von Willebrand's disease (p. 1317) and may be found, though rarely, in a number of conditions in which coagulation time is prolonged, provided the blood and tissues are severely impoverished in coagulation factors (see Table 24-4, Chap. 24, p. 228). These include hemophilia and hypoprothrombinemia. A positive tourniquet test is found in many circumstances other than thrombocytopenic purpura (p. 227). Poor retraction of the clot is found, with rare exceptions, only when the platelets are reduced in number. The combination of these abnormalities is characteristic of thrombocytopenic purpura.

Before a diagnosis of purpura hemorrhagica can be made, however, the recognized causes of thrombocytopenic purpura must be excluded. They are listed in Table 238-1. The history and physical examination will serve to rule out many of these conditions. Adenopathy and sternal tenderness, as well as anemia out of proportion to the blood loss, even in the absence of striking changes in the leukocytes, should suggest leukemia. Persistent leukopenia suggests leukemia, aplastic anemia, disseminated lupus erythematosus, or one of the splenic disorders.

Treatment and Prognosis. The first principles in the therapy of thrombocytopenic purpura are expectant management and a search for possible etiologic factors. If one is found or suspected, further exposure should be stopped. Expectant therapy, in addition to appropriate rest, nursing, and diet, includes iron if there has been blood loss, and blood transfusion if this loss has been severe. The use of siliconized apparatus or plastic equipment in transfusion or the use of platelet-rich blood, or both, is helpful as a temporary measure, but it is noteworthy that platelet transfusions have limited value, since platelet survival tends to decrease progressively when repeated transfusions are given.

These measures are recommended because spontaneous remissions are common, especially in children. They can be complete and permanent. Remissions are particularly likely to occur if the onset has been acute and there is no history of previous hemorrhagic manifestations. Unfortunately the danger of bleeding into a vital organ such as the brain makes the waiting period a trying one. Recurrences are twice as common in females as in males. A more or less chronic course, punctuated perhaps by more acute phases, is more often seen in adolescents and adults but occurs at all ages.

The use of adrenocorticotrophic hormone, cortisone, or prednisone is often associated with a decrease of bleeding phenomena and the thrombocytopenia may decrease or disappear, but these effects are temporary. These hormones are useful chiefly, therefore, in the management of hemorrhagic emergencies and in the preoperative preparation of patients for splenectomy. Those which can

Table 238-1. CLASSIFICATION OF THROMBOCYTOPENIC PURPURAS

- I. "Essential" or "primary" purpura hemorrhagica; idiopathic thrombocytopenic purpura (ITP)
- II. Symptomatic purpuras
 - A. Chemical, vegetable, animal, and physical agents
 1. Chemical
 - a. Myelosuppressive agents: nitrogen mustards, TEM, busulfan, urethan, antimetabolites, benzol
 - b. Agents which in therapeutic doses produce purpura mainly because of individual sensitivity: organic arsenicals, Sedormid, quinidine, quinine, sulfonamides, gold salts, chlorothiazide (Diuril), hydrochlorothiazide, butobarbitone; and possibly also acetazolamide (Diamov), chloramphenicol, penicillin, chlorophenothane (DDT), meprobamate (Equanil, Miltown), etibopfen, oxytetracycline, para-aminosalicylic acid, streptomycin, phenylbutazone, antipyrine, sodium salicylate, tridione, meprobarnol, phenobarbital, allyl-isopropylbarbituric acid, thiourea, dinitrophenol, digitoxin, mercurials, potassium iodide, bismuth, ergot, organic hair dyes, estrogens, tolbutamide (Orinase), chlorpropamide (Diabinese)
 2. Vegetable: Foods, orris root
 3. Animal: Snake venoms, pertussis vaccine, insect bite
 4. Physical: X-rays and other forms of ionizing radiation, heat stroke, extensive burns

be given orally are preferred. In general 75 to 250 mg cortisone or 20 to 60 mg prednisone is given per day, in divided doses.

Splenectomy results in "cure" in approximately two-thirds of patients. Following splenectomy the platelet count may increase rapidly and to abnormally high levels or, more often, it may rise gradually. Bleeding often ceases even though the platelet count may not have increased greatly, an effect which suggests an influence of the spleen on capillary function. In the bone marrow the previously abnormal megakaryocytes in most instances soon appear to be quite normal again and are seen to be surrounded by platelets. Even when splenectomy is not followed by complete recovery, considerable improvement can be expected.

Splenectomy is indicated (1) in those cases of idiopathic thrombocytopenic purpura in which spontaneous remission has not occurred after six or more months' observation and the clinical manifestations are moderate or severe, (2) in patients who appear to respond to steroid therapy but require relatively large doses to maintain a clinical state devoid of serious hemorrhage and who have shown no tendency to spontaneous remission in 6 to 12 months of observation; (3) in the rare patient whose growth and development or social or economic status is seriously impaired by recurrences; (4) in a woman in the later stages of pregnancy, if the condition is severe and if other measures have failed; (5) in secondary forms of thrombocytopenic purpura in which the cause cannot be treated or removed and yet the bleeding manifestations are severe (e.g., some cases of Gaucher's disease). The operation is not indicated (1) early in the first episode, especially in children, since spontaneous recovery is much more common than the reverse; (2) in most cases of symptomatic purpura; (3) in neonatal purpura, since recovery takes place naturally; (4) in cases in which the diagnosis has not been established clearly; and, some would add, (5) in acute fulminating cases since mortality then is high. However, others consider this to be an indication for emergency splenectomy, and the question must be considered unsettled. Claims that splenectomy causes "dissemination" of unrecognized lupus erythematosus and increases the hazard of infection have not been substantiated convincingly.

In patients with idiopathic thrombocytopenic purpura other operations should not be carried out before splenectomy has been done, since the bleeding may be severe and serious.

NONTHROMBOCYTOPENIC PURPURAS

A number of types of purpura are not accompanied by thrombocytopenia.

Some of these purpuras have been discussed already (p. 223), but allergic purpura and certain

other rare purpuric disorders deserve more complete consideration.

Allergic Purpura

In this form of purpura there is found one or more of the common symptoms of allergy such as erythema, urticaria, or effusions of serum into subcutaneous or submucous tissues or viscera. There may be concomitant articular symptoms (Schönlein's purpura, *peliosis rheumatica*), crises of abdominal pain (*Henoch's purpura*), or no localized signs (*purpura simplex*). Constitutional symptoms such as fever and malaise may be present. The manifestations may wax and wane in intensity, extent, and nature. In various combinations, erythema (multiforme, bullosum, vesiculosum, nodosum), urticaria, and edema may be encountered. Necrotic areas may develop, to be followed by the formation of bullae or ulcers. The skin lesions may appear in crops and may be accompanied by itching or paresthesias. There may be hemorrhage from the visible mucous membranes. Kidney lesions similar in nature to those found in the skin may develop and cause hematuria, proteinuria, and profound though temporary disturbance of renal function.

Etiology and Pathogenesis. These purpuras are more common in children and young adults than in older age groups. The true nature of these purpuras is unknown. The resemblance to serum sickness suggests an allergic basis, but only in a minority has an allergic cause been demonstrated. In some cases the exciting agent appears to have been bacterial (streptococcus, antityphoid vaccine) or an article of food (milk, eggs, pork, strawberries, etc.). In others, hypersensitivity to cold has appeared to be the factor. Comparison of the sex ratio, age of onset, seasonal trends, and incidence of previous upper respiratory tract infections, particularly those associated with a hemolytic streptococcus, and similarities in the latent period before the onset of symptoms suggest a close relationship between the Henoch-Schönlein syndrome and acute nephritis.

It is likely that an antigen-antibody reaction occurs which takes place especially in the endothelium of certain blood vessels. As a result, there is an alteration in the permeability of the small blood vessels. Perivascular inflammation has been observed about the small vessels of the corium of the skin. The various manifestations arise from extravasations of varying proportions of plasma and formed elements of the blood. Mechanical factors may possibly influence the localization of the lesions in addition to the local vascular changes. In Henoch's purpura, an urticarial, hemorrhagic effusion into the intestinal wall is of the colicky, pain and sometimes etc.

Diagnosis. Diagnosis is purpura is not present

of the colicky, intestinal affection. with purpura. Henoch's

Table 238-2. CLASSIFICATION OF NONTHROMBOCYTOPENIC PURPURAS

- I. Allergic purpura: Purpura of Henoch and Schönlein, erythemas of Osler
- II. Symptomatic purpura
 - A. Infections: Subacute bacterial endocarditis, meningococcemia, staphylococemia, typhoid fever, rheumatic fever, scarlet fever, smallpox, measles, diphtheria, Rocky Mountain spotted fever
 - B. Chemical and animal agents: Iodides, belladonna, atropine, quinine, procaine penicillin, bismuth, mercury, copaiba, phenacetin, salicylic acid, merbaphen, chloral hydrate and other hypnotics; snake venoms
 - C. Avitaminosis: scurvy
 - D. Certain skin diseases: Ehlers-Danlos syndrome, annular telangiectatic purpura, etc.
 - E. Chronic diseases: renal, cardiac, hepatic; hemochromatosis, Cushing's syndrome, polycythemia vera; generalized amyloidosis, blood-borne carcinoma emboli
 - F. Various forms of dysglobulinemia: multiple myeloma, cryoglobulinemia, hyperglobulinemia, macroglobulinemia; purpura hyperglobulinemia
- III. Purpuric disorders associated with qualitative abnormalities of platelets. Thrombocytopathic purpuras
 - A. Prolonged bleeding time: von Willebrand's disease. Constitutional thrombopathy
 - B. Other thrombocytopathies, congenital and acquired
 - C. Defective clot retraction. Glanzmann's thrombasthenia
 - D. Unclassified varieties
- IV. Purpura associated with increased capillary fragility
 - A. Hereditary familial purpura simplex
 - B. Unclassified varieties
- V. Purpura associated with increased number of platelets. Hemorrhagic thrombocytopenia
- VI. Miscellaneous forms of purpura
 - A. Purpura simplex, purpura senilis, purpura eachectica, mechanical purpura, orthostatic purpura
 - B. Purpura fulminans
 - C. Purpura in women. Vicarious bleeding. Autoerythrocyte sensitization

purpura, crises of pain may develop which, in the absence of purpura and accompanied as they may be by leukocytosis, cannot be clearly distinguished from acute abdominal conditions which call for operative intervention. Eosinophilia may be present, and then an allergic rather than an inflammatory reaction may be suspected. Acute nephritis may be simulated when the kidney is involved. Hematuria may be a prominent symptom in such cases, just as melena may occur in Henoch's purpura. The

Schönlein type may be mistaken for rheumatic fever.

When purpura is discovered and there are exudative skin lesions at the same time, diagnosis is much easier, since these lesions are not encountered in other forms of purpura as a rule. Various chemical agents (e.g., quinine) may also produce nonthrombocytopenic purpura (Table 238-2). Furthermore, this may be a symptom of a variety of diseases, already discussed (p. 223).

Treatment and Prognosis. Treatment is purely symptomatic. Naturally, if an etiologic agent is discovered or suspected, further exposure should be eliminated. Desensitization may be attempted if the exciting agent is protein in nature. Allergic purpura is rarely fatal. Individual attacks last from 1 to 6 weeks. Recurrences at intervals of months or years are not unusual, however, and in some cases glomerulonephritis has developed in association with or in the wake of the purpuric disorder, with the consequences usual in that condition. Results of hormone therapy (ACTH, adrenocorticosteroids) have been equivocal or disappointing.

Other Hemorrhagic (Purpuric) Disorders

A variety of hemorrhagic disorders characterized in the main by spontaneous bleeding from the mucous membranes and from the internal surfaces of the body, and often by petechiae and ecchymoses as well, have been described which cannot be fitted into the categories already discussed. Posttraumatic and postoperative bleeding is not unusual in these cases. Of these conditions, von Willebrand's disease and Glanzmann's thrombasthenia are becoming better defined as entities.

Von Willebrand's disease, a hemorrhagic diathesis inherited as a simple mendelian dominant trait and affecting both sexes, is characterized by prolonged bleeding time, normal platelet count, normal coagulation time, and normal clot retraction. The tourniquet test may or may not be positive. The tendency to bleed appears early in childhood and takes the form of epistaxis, bleeding from the gums, or from the female genitalia. Hemorrhage from the gastrointestinal or urinary tract may occur, and there may be prolonged bleeding from injuries and operation sites.

The discovery that similar cases might be associated with a deficiency of factor VIII, the anti-hemophilic globulin, led to the introduction of the terms *vascular hemophilia* and *angiohemophilia*. It is possible that von Willebrand's disease and angiohemophilia represent a single entity with variable expressivity. The underlying heritable defect is obscure. Cases have been described with morphologic defects in the platelets, or functional abnormality, or distorted and bizarre capillaries which fail to contract following injury.

The term *thrombocytopathy* has been applied to disorders characterized by deficient platelet functional activity. The platelet abnormality is *qualitative* rather than quantitative, as in the thrombocytopenias. Von Willebrand's disease is thought to represent one form of constitutional thrombocytopathy. Faulty platelet function may also develop in association with various clinical states, such as uremia ("acquired thrombocytopathy").

Glanzmann's *thrombasthenia*, another form of constitutional thrombocytopathy, refers to excessive hemorrhage in which the bleeding time, platelet count, and coagulation time are normal but clot retraction is poor and the morphology of the platelets is abnormal. Several varieties have been described. Thus, in the so-called *Glanzmann-Naegeli* type of thrombasthenia, small round platelets, normal or increased in number but with impaired adhesiveness and agglutinability have been described. By electron microscopy it has been observed that the platelets are unable to form pseudopods or to spread in contact with a wettable surface. Enzymatic deficiencies and reduced levels of adenosine triphosphate (ATP) have been demonstrated in the platelets in one group of cases; evidence has been given of defective utilization of ATP in other cases.

Surgical procedures in cases such as these should be avoided. Bleeding is managed by pressure, the application of thrombin-fibrin foam, and blood transfusion, when necessary.

Hemorrhagic thrombocythemia is a strange and rare disorder in which hemorrhagic phenomena occur in spite of the presence of greatly excessive numbers of platelets. The spleen may be enlarged and leukocytosis of marked degree may also be present.

239 HEMOPHILIA AND RELATED DISORDERS

M. M. Wintrobe

HEMOPHILIA

Definition. Hemophilia is a constitutional anomaly of blood coagulation which depends on the inheritance of a sex-linked, recessive mendelian trait transmitted by the female and affecting only males. It is characterized by a lifelong tendency to excessive bleeding. The coagulation time is prolonged.

History. A clear description of this disorder was published in 1803 by Otto of Philadelphia. However, it is apparent from passages in the Talmud that the condition was known to the ancient Jews, who even proscribed circumcision in those whose family history suggested this disorder.

Etiology and Pathogenesis. The factor or gene responsible for the development of hemophilia appears to be carried in the X chromosome of the reproductive cells. The disease is limited to the male and is transmitted from the male through an unaffected daughter to her son. The daughters of an affected male transmit the trait as an evident defect to half their sons and as a hidden (recessive) characteristic to half their daughters. The occurrence of hemophilia in the female would require the marriage of a hemophilic male with a carrier female. Such cases have been described, but they

are exceedingly rare. Sporadic cases of hemophilia have been observed in which the family history was negative. These can sometimes be explained by long inheritance through females with the males being, by chance, unaffected. Illegitimacy may be responsible for other instances, while still others may represent the disease arising *de novo*.

It is generally accepted that the abnormality in hemophilia is due to the absence or reduction in the blood of a component essential for the formation of plasma thromboplastin (factor VIII, antihemophilic globulin). The role which this substance plays in the process of coagulation was discussed earlier (Chap. 24).

Symptomatology. Hemorrhage, usually following trauma but sometimes spontaneous, is the essential symptom. The bleeding is in the nature of a persistent, slow oozing which is out of all proportion to the extent of the injury. This tendency to prolonged bleeding usually appears in early childhood, even in infancy. The bleeding may last not only hours but days and even weeks, and may lead to profound anemia. Subcutaneous and intramuscular hemorrhages are common. Petechiae are very rare. Hematomas may be large. There may be severe bleeding from the mouth, gums, lips, tongue, or gastrointestinal tract. Epistaxis is a common symptom. The eruption and loss of teeth may be accompanied by severe bleeding. Hematuria is relatively common and hemorrhage into joints is characteristic. Recurrences are the rule, and ultimately a permanently swollen joint with local deformity, contractures, and muscular atrophy are produced.

The blood in typical cases is normal except for the prolonged coagulation time and the manifestations which hemorrhage produces (p. 1278). Curiously, the degree of prolongation of coagulation time, like the symptoms of this disorder, varies from time to time. Platelets are normal in number. Only rarely is bleeding time prolonged.

It has been shown that cases of hemophilia occur which are less severe than the classic type just described. Assays of plasma antihemophilic globulin (AHG) have shown a great range in the quantity of this essential substance. Four grades of hemophilia have been distinguished, viz., classical hemophilia, in which the plasma AHG is 0 per cent; moderate hemophilia, characterized by the occurrence of subcutaneous hematomas and postoperative hemorrhages, essentially normal coagulation time, normal prothrombin consumption, and less than 3 per cent AHG; mild hemophilia, in which coagulation time and prothrombin consumption are normal and the plasma AHG is approximately 16 per cent; and subhemophilia, in which there may only be a history of prolonged postoperative oozing. The plasma AHG is in the neighborhood of 33 per cent, as compared with the normal value of 65

to 136 per cent. Frequently the severity of the disorder is constant in a given family, as if not only the defect but also its degree were an inherited characteristic.

The bone marrow is normal except for normoblastic hyperplasia when hemorrhage has been severe.

Diagnosis. Although hemophilia and purpura hemorrhagica are often confused with each other, differentiation is easy as a rule, for the latter condition involves thrombocytopenia, prolonged bleeding time, poor clot retraction, and a positive tourniquet test. In hemophilia the patient is normal in these respects and, in the classical disorder, coagulation time is prolonged. There is, in addition, the history of repeated, protracted hemorrhage, usually first manifested in early childhood, as well as the characteristic family history. Occasionally difficulty in diagnosis may arise if attention is attracted only to the joint manifestations or to a swelling not recognized as a hematoma. In a similar manner, the bleeding may suggest kidney disease, pulmonary disease, or peptic ulcer.

Other Disorders of Coagulation. The development of more precise methods of laboratory examination has resulted in the discovery of new entities, hitherto confused with classic hemophilia and the purpuras, in addition to recognition of the fact that mild forms of hemophilia exist. Many of these disorders were mentioned earlier (Chap. 24). The results of various laboratory tests in a number of these conditions are presented in Table 239-1.

In cases of hemophilia with normal or only slightly impaired coagulation time, the prothrombin consumption test will be found reliable and sensitive, although it is not specific; reduced prothrombin consumption is found also in various disorders associated with thrombocytopenia, as well as in patients with hemorrhagic manifestations due to anticoagulants affecting thromboplastic activity. The absence of a circulating anticoagulant can be demonstrated by adding the patient's blood in varying proportions to normal blood. The clotting of normal blood is not delayed by the addition of even 50 per cent of hemophilic blood.

The one-stage prothrombin time separates hemophilia from conditions associated with true prothrombin, factor V, factor VII, and factor X deficiencies, and also from many cases in which there is a circulating anticoagulant. In hemophilia, in contrast to these conditions, prothrombin time is normal. The deficiency in hemophilic blood can be corrected by the addition of a small proportion of normal plasma. The degree of reduction in antihemophilic globulin content can be assayed roughly by this means.

It was pointed out earlier that assays for antihemophilic globulin have revealed a mild form of

Table 230-1. BLEEDING AND COAGULATION TESTS IN SOME OF THE HEMORRHAGIC DISORDERS

Disease or condition	Thrombocytopenia	Bleeding time prolonged	Clot retraction poor	Tourniquet test positive	Coagulation time prolonged	Prothrombin time (one-stage) prolonged	Prothrombin consumption impaired and thromboplastic generation reduced

* May be prolonged if condition is severe.

† May be normal if condition is mild.

hemophilia in which even prothrombin consumption is normal or equivocal. An additional observation of interest is that, unlike classic hemophilia, some of the heterozygotes show a diminution in antihemophilic globulin, a finding which suggests that the gene is not completely recessive, as it is in classical hemophilia, and for this reason the condition has been attributed to an allelic mutant of the hemophilia gene.

The unequivocal identification of *female carriers* of hemophilia cannot be made by present methods, but low levels of antihemophilic globulin have been demonstrated in a number of female carriers. Furthermore, some female carriers have an unusual tendency to bleed.

A number of disorders are now recognized which involve the first stage of coagulation. To distinguish these from one another the thromboplastin generation test is especially useful. Thus *factor IX deficiency* [plasma thromboplastin component (PTC) deficiency, Christmas disease] is clinically indistinguishable from classic hemophilia. This disorder is due to the lack or deficiency of a coagulation factor necessary for the formation of thromboplastin which is present in normal and in hemophilic plasma. Both severe and mild forms of the disorder have been encountered. The coagulation time is usually prolonged, and prothrombin consumption is impaired, but cases with normal values have also been observed. The missing coagulation factor is most readily obtained from serum. Since

this condition resembles hemophilia in its clinical manifestations and mode of inheritance, it has been called *hemophilia B*, the letter A being used to refer to the classic condition. The two types of hemophilia can be distinguished *in vitro* by the correction of the coagulation defect of the one by the other, and of both by the addition of normal plasma. Another simple test consists in the correction of the clotting defect in PTC deficiency by the addition of normal serum and the failure of such correction in classical hemophilia.

Still other disorders resembling hemophilia have been described. They include *plasma thromboplastin antecedent (PTA) deficiency*, which differs from hemophilia and PTC deficiency in that the manifestations occur in *either sex*. The condition appears to be transmitted as an autosomal dominant trait with a high degree of penetrance but variable expression. Spontaneous bleeding is rare; bleeding has occurred usually following trauma or a surgical procedure, including tooth extraction. Various degrees of severity have been observed, ranging from a severe form with prolonged coagulation time and markedly abnormal prothrombin consumption, to a mild form with normal coagulation time and only slightly impaired prothrombin consumption. Thromboplastin generation is markedly impaired. The deficiency in this disorder is corrected both by plasma absorbed with BaSO₄, which corrects factor VIII (AHG) deficiency, and by serum, which corrects factor IX (PTC) defi-

ciency. PTA is a globulin which is stable on storage and is present in normal serum, where it is localized in the β_2 -globulin fraction. Studies of the relative incidence of hemophilia, PTC, and PTA deficiencies have yielded ratios of approximately 10:2:1.

Course and Prognosis. The tendency to bleed varies from time to time and differs in degree from one family to another. The typical hemophilic patient rarely survives to adulthood without suffering some disabling deformity of the joints. The prognosis differs, however, in accordance with the severity of the deficiency. Death may occur from exsanguination following surgical procedures or accidental cuts. Less often it is due to internal hemorrhage.

Treatment. The prevention of hemophilia, whether due to factor VIII or factor IX deficiency, depends on appropriate restriction of marriage or at least of propagation. Only unaffected males can marry with any assurance that the hemorrhagic tendency will not be transmitted.

Affected individuals and male children of tainted stock must be guarded against trauma, and surgical measures, even the most minor ones, should be avoided whenever possible. If some procedure which may entail bleeding is absolutely necessary, it should be done only in a hospital and with plentiful amounts of fresh blood and plasma available. Normal plasma, kept solid or dried lyophilically within a few hours of its withdrawal from the body, will retain its antihemophilic effect almost indefinitely. Although as little as 50 ml fresh plasma will maintain the coagulation time of a hemophilic of moderate severity within normal limits for about 24 hr, in practice it is wise to use much larger amounts. Therapeutic failures are almost always attributable to the administration of too little blood or plasma, to the too wide spacing of transfusions (intervals longer than 6 hr), and to the too early interruption of therapy. The administration of blood should be continued for several days after bleeding seems to have ceased. Unfortunately no satisfactory source of antihemophilic factors is readily available other than whole blood or plasma. When internal bleeding occurs, transfusions of blood and plasma are the only measures of value and carry the minimum of risk. Surgery is contraindicated. Prior to any surgical measure, such as tooth extraction, at least 500 ml fresh plasma should be given. In contrast to its effectiveness in PTC deficiency, serum is devoid of activity in classic hemophilia.

An essential in the local management of bleeding in hemophilia is the avoidance of tissue injury. The existence of damaged or devitalized tissue merely prolongs the period of subsequent hemorrhage. Thus, for example, in dental extraction, gum margins should not be sewn together. When there

is free bleeding, pressure must naturally be applied, but it should be temporary and gentle and should be supplemented by the use of coagulants such as Russell's viper venom or thrombin ("hemostatic globulin"). These measures may be followed by the application of absorbable hemostatic dressings such as human fibrin, fibrin foam, gelatin sponge, or oxidized cellulose. Following tooth extraction, a previously made dental splint will keep the dressing in place with a minimum of movement.

Unfortunately, in some patients with hemophilia antibodies with an anticoagulant action have developed following repeated transfusions. This appears to be due to immunization against the anti-hemophilic factor.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Definition. This is a vascular anomaly characterized by multiple dilatations of capillaries and venules in the skin and mucous membranes. The anomaly is transmitted as a simple dominant trait by both sexes.

Etiology. The telangiectases may be found in childhood, but they increase in number as age advances. Bleeding may not commence until adult life has been reached.

Symptomatology. Epistaxis is especially common, but bleeding may come from telangiectases wherever they are: the face, tongue, lips, or gastrointestinal, respiratory, or genitourinary tracts. Those on the skin are less likely to bleed than are telangiectases on mucous membranes. The telangiectases range from pin point to about 3 mm in diameter, are bright red or violaceous in color, and characteristically blanch on pressure. Sometimes they form nodular vascular tumors the size of a split pea, such lesions resemble those of a very rare, probably systemic condition, angokeratoma corporis diffusum (Fabry), which may be due to a hereditary defect in lipid metabolism and in which there is widespread involvement of the media of the blood vessels, with manifestations in the renal, pulmonary, and other systems of the body. In elderly patients some of the lesions of hereditary telangiectasia may become spiderlike, resembling those associated with hepatic insufficiency. Trivial trauma sustained by these abnormal, relatively exposed vessels results in an unusual amount of bleeding. The blood is normal except for the effects hemorrhage may have produced. The tourniquet test is negative.

Diagnosis. This depends on recognition of the vascular anomalies, which are easily overlooked. Purpuric spots do not fade on pressure.

In a number of cases of this disorder pulmonary arteriovenous fistula has been observed.

Treatment. The telangiectatic vessels are excessively fragile, but oxidized cellulose (Oxycel), Gelfoam, or similar hemostatic agents usually suffice to control an existing hemorrhage if they are applied carefully. Although the primary bleeding site can be cauterized or destroyed by electrocoagulation, satellite lesions soon form nearby. Prophylaxis is unsatisfactory. Many procedures have been tried, including estrogen and androgen therapy, with doubtful effect.

240 AGRANULOCYTOSIS AND THE PANCYTOPENIAS

M. M. Wintrobe

AGRANULOCYTOSIS

Definition. Agranulocytosis (agranulocytic anemia) is a disorder characterized by severe sore throat, marked prostration, and extreme reduction or even complete disappearance of the granulocytes from the blood. This clinical picture, first recognized by Schultz in 1922, was observed most frequently in women of middle age and often ended in sepsis

and death. An etiologic relationship to the taking of certain drugs has been demonstrated.

Etiology and Pathogenesis. In 1931 Kracke pointed out that the sudden appearance of this syndrome corresponded with the introduction of certain coal-tar derivatives as therapeutic agents. This was borne out by considerable circumstantial evidence which incriminated, in particular, the antipyretic, aminopyrine (Pyramidon). The course of events in affected individuals would seem to be (1) granulocytopenia as the result of some effect induced by the drug; (2) loss of resistance to infection, development of sore throat; (3) overwhelming sepsis and death. That some form of tissue injury, in addition to leukopenia, may be a factor in the pathogenesis of this syndrome is suggested by the frequency with which one may encounter leukopenia, even of severe degree, following nitrogen mustard therapy without sepsis developing.

The most striking change observed in the bone marrow is a lack of juvenile and segmented neutrophilic leukocytes, less mature forms being plentiful. This picture has been referred to as "maturation arrest," but it could as readily result from abnormal peripheral destruction of the leukocytes or their segregation somewhere.

Drugs producing leukopenia may be divided into two main groups—namely, those which produce this effect in all individuals if given in sufficient amounts, and those which cause leukopenia only in certain "sensitive" persons (Table 240-1). Various data suggest that between 0.5 and 4 per cent of patients taking the second group of drugs develop granulocytopenia. In group III are listed drugs which have been incriminated in a few case reports but which cannot be regarded as well-established causes of leukopenia.

It is likely that granulocytopenia develops by more than one mechanism. Some cases are encountered in which no drug seems to be incriminated. Those drugs which produce granulocytopenia in all persons when given in sufficient amounts probably do so through their toxic effects. Agents such as aminopyrine probably require a peculiar sensitivity or idiosyncrasy on the part of the patient. Rarely other manifestations of sensitivity, such as rash, urticaria, and edema, may be present or may have occurred on other occasions. Furthermore, in patients who have recovered from aminopyrine-induced agranulocytosis, the administration of small amounts (0.2 Gm) of the drug may be followed within 6 to 10 hr by disappearance of all the neutrophils from the blood. It has also been shown that the blood of such a person, withdrawn 3 hr following ingestion of the drug, produces outspoken granulocytopenia within 20 to 40 min after its transfusion into normal persons. In the plasma and serum of the sensitive patient a sub-

Table 240-1. LEUKOPENIA-PRODUCING DRUGS

Group I—regularly produce leukopenia if given in sufficient amounts

Mustards (sulfur and nitrogen mustards, TEM, etc.)
 Urethan, busulfan, Demecolcin
 Antimetabolites (antifolate acid compounds, 6-mercaptopurine, etc.)
 Benzene

Group II—produce leukopenia in "sensitive" persons only

Analgesics (aminopyrine, phenylbutazone, etc.)
 Antithyroid drugs (thiouracil, methimazole, etc.)
 Anticonvulsants (trimethadione, methenylate, etc.)
 Sulfonamides (sulfanilamide, sulfisoxazole (Gantrisin), etc.)
 Antihistamines (Pyribenzamine, phenothiazine, etc.)
 Antimicrobial agents (organic arsenicals, chloramphenicol)
 Tranquilizers (chlorpromazine, etc.)
 Miscellaneous (divitrophenol, tolbutamide, gold salts, etc.)

Group III—very rarely cause leukopenia, if at all

Barbiturates (acetanilid, acetophenetidin)
 Quinine
 Cinchophen, etc.

stance has been found at the height of the aminopyrine granulocytopenia which produces agglutination of homologous and heterologous leukocytes. If, as seems likely, an immune mechanism is involved in the pathogenesis of this type of granulocytopenia, removal of the agglutinated leukocytes from the circulating blood may be postulated, with resulting depletion of the more mature forms from the bone marrow.

Symptomatology. The condition described by Schultz was an *acute, fulminating disorder*. In such cases there may be a prodromal period, marked only by malaise or moderate fever, which often is overlooked. If the granulocytopenia is recognized at this stage, and sepsis is prevented or does not develop, no other manifestations may appear. If infection supervenes or if the condition is first recognized at this stage, the onset appears to be sudden and is marked by a chill, high fever, and often sore throat. Prostration is extreme. Gangrenous ulceration may be found on the gums, tonsils, soft palate, lips, pharynx, or buccal mucous membranes. Regional adenopathy may be present, but generalized adenopathy and sternal tenderness are not found, and splenomegaly, when present, is minimal. Brawny edema of the neck can become extreme. Necrosis of the gastrointestinal tract may occur. Jaundice has been described in some cases. In fatal cases the duration of the illness is 3 to 9 days.

In the blood, granulocytopenia is the outstanding finding. Since the leukocyte count is usually under 3,000 per cu mm and often is as low as 500, a reduction in the absolute number of all cells actually takes place. Of the leukocytes which re-

main, 95 to 100 per cent may be lymphocytes. Anemia and thrombocytopenia are not found; if they are present, another cause should be suspected.

The bone marrow is normal except for the "maturation arrest" described already.

In addition to the acute form, described above, *chronic, cyclic, and recurrent* forms of granulocytopenia, as well as *familial, transitory neonatal, childhood*, and other rare varieties, have been observed. They may or may not be related to the acute disorder. In the chronic cases the course is prolonged, and infections which often are relatively resistant to therapy, especially in the skin and oral cavity, occur repeatedly. Hypoplasia of granulocytic precursors in the bone marrow, slight splenomegaly, and absolute lymphocytosis and monocytosis have been described. In other instances there is a cyclic or recurrent periodicity of attacks at intervals of weeks or months, with more or less normal leukocyte counts in the symptom-free period. Unexplained fatigue is a common complaint. In some cases the leukopenia has been observed to occur in remarkably regular, 3-week cycles (*periodic neutropenia*).

Primary splenic neutropenia is a name applied to a clinical picture characterized by fever, pain over the splenic region and splenic enlargement, granulocytopenia, and essentially normal or somewhat hyperplastic bone marrow. The manifestations may be acute, subacute, or chronic and have been attributed to excessive lysis of neutrophils by the spleen. Splenectomy is reported as bringing complete relief, and excessive phagocytosis of leukocytes has been described in the spleen. The disorder is very rare.

Diagnosis. The clinical picture may suggest a variety of buccal and pharyngeal infections. The great majority of these infections, however, are accompanied by leukocytosis. Infections characteristically accompanied by leukopenia, such as measles, undulant fever, and typhoid, should rarely give difficulty, although influenza may. "Alekemic" leukemia may present a similar clinical picture, but sternal tenderness, general glandular enlargement, and splenomegaly, as well as anemia, thrombocytopenia, and, usually, very immature leukocytes in the blood, make differentiation no serious problem. Aplastic anemia is recognized by evidence of involvement of red corpuscles and platelets as well as leukocytes.

Treatment and Prognosis. The offending drug must be searched for and its further use prohibited. Of equal importance is the administration of chemotherapeutic agents, such as penicillin, which will hold the infection in abeyance until leukocyte formation becomes normal and is able to cope with the offending organisms. There is no conclusive evidence that various agents which have been pro-

Treatment. The telangiectatic vessels are excessively fragile, but oxidized cellulose (Oxycel), Celfoam, or similar hemostatic agents usually suffice to control an existing hemorrhage if they are applied carefully. Although the primary bleeding site can be cauterized or destroyed by electrocoagulation, satellite lesions soon form nearby. Prophylaxis is unsatisfactory. Many procedures have been tried, including estrogen and androgen therapy, with doubtful effect.

240 AGRANULOCYTOSIS AND THE PANCYTOPENIAS

M. M. Wintrobe

AGRANULOCYTOSIS

Definition. Agranulocytosis (agranulocytic anemia) is a disorder characterized by severe sore throat, marked prostration, and extreme reduction or even complete disappearance of the granulocytes from the blood. This clinical picture, first recognized by Schultz in 1922, was observed most frequently in women of middle age and often ended in sepsis

and death. An etiologic relationship to the taking of certain drugs has been demonstrated.

Etiology and Pathogenesis. In 1931 Kracke pointed out that the sudden appearance of this syndrome corresponded with the introduction of certain coal-tar derivatives as therapeutic agents. This was borne out by considerable circumstantial evidence which incriminated, in particular, the antipyretic, aminopyrine (Pyramidon). The course of events in affected individuals would seem to be (1) granulocytopenia as the result of some effect induced by the drug; (2) loss of resistance to infection, development of sore throat; (3) overwhelming sepsis and death. That some form of tissue injury, in addition to leukopenia, may be a factor in the pathogenesis of this syndrome is suggested by the frequency with which one may encounter leukopenia, even of severe degree, following nitrogen mustard therapy without sepsis developing.

The most striking change observed in the bone marrow is a lack of juvenile and segmented neutrophilic leukocytes, less mature forms being plentiful. This picture has been referred to as "maturation arrest," but it could as readily result from abnormal peripheral destruction of the leukocytes or their segregation somewhere.

Drugs producing leukopenia may be divided into two main groups—namely, those which produce this effect in all individuals if given in sufficient amounts, and those which cause leukopenia only in certain "sensitive" persons (Table 240-1). Various data suggest that between 0.5 and 4 per cent of patients taking the second group of drugs develop granulocytopenia. In group III are listed drugs which have been incriminated in a few case reports but which cannot be regarded as well-established causes of leukopenia.

It is likely that granulocytopenia develops by more than one mechanism. Some cases are encountered in which no drug seems to be incriminated. Those drugs which produce granulocytopenia in all persons when given in sufficient amounts probably do so through their toxic effects. Agents such as aminopyrine probably require a peculiar sensitivity or idiosyncrasy on the part of the patient. Rarely other manifestations of sensitivity, such as rash, urticaria, and edema, may be present or may have occurred on other occasions. Furthermore, in patients who have recovered from aminopyrine-induced agranulocytosis, the administration of small amounts (0.2 Gm) of the drug may be followed within 6 to 10 hr by disappearance of all the neutrophils from the blood. It has also been shown that the blood of such a person, withdrawn 3 hr following ingestion of the drug, produces outspoken granulocytopenia within 20 to 40 min after its transfusion into normal persons. In the plasma and serum of the sensitive patient a sub-

In the blood, granulocytopenia is the outstanding finding. Since the leukocyte count is usually under 3,000 per cu mm and often is as low as 500, a reduction in the absolute number of all cells actually takes place. Of the leukocytes which re-

main, 95 to 100 per cent may be lymphocytes. Anemia and thrombocytopenia are not found; if they are present, another cause should be suspected.

The bone marrow is normal except for the "maturation arrest" described already.

In addition to the acute form, described above, *chronic, cyclic, and recurrent* forms of granulocytopenia, as well as *familial, transitory neonatal, childhood*, and other rare varieties, have been observed. They may or may not be related to the acute disorder. In the chronic cases the course is prolonged, and infections which often are relatively resistant to therapy, especially in the skin and oral cavity, occur repeatedly. Hypoplasia of granulocytic precursors in the bone marrow, slight splenomegaly, and absolute lymphocytosis and monocytosis have been described. In other instances there is a cyclic or recurrent periodicity of attacks at intervals of weeks or months, with more or less normal leukocyte counts in the symptom-free period. Unexplained fatigue is a common complaint. In some cases the leukopenia has been observed to occur in remarkably regular, 3-week cycles (*periodic neutropenia*).

Primary splenic neutropenia is a name applied to a clinical picture characterized by fever, pain over the splenic region and splenic enlargement, granulocytopenia, and essentially normal or somewhat hyperplastic bone marrow. The manifestations may be acute, subacute, or chronic and have been attributed to excessive lysis of neutrophils by the spleen. Splenectomy is reported as bringing complete relief, and excessive phagocytosis of leukocytes has been described in the spleen. The disorder is very rare.

Diagnosis. The clinical picture may suggest a variety of buccal and pharyngeal infections. The great majority of these infections, however, are accompanied by leukocytosis. Infections characteristically accompanied by leukopenia, such as measles, undulant fever, and typhoid, should rarely give difficulty, although influenza may. "Aleukemic" leukemia may present a similar clinical picture, but sternal tenderness, general glandular enlargement, and splenomegaly, as well as anemia, thrombocytopenia, and, usually, very immature leukocytes in the blood, make differentiation no serious problem. Aplastic anemia is recognized by evidence of involvement of red corpuscles and platelets as well as leukocytes.

Treatment and Prognosis. The offending drug must be searched for and its further use prohibited. Of equal importance is the administration of chemotherapeutic agents, such as penicillin, which will hold the infection in abeyance until leukocyte formation becomes normal and is able to cope with the offending organisms. There is no conclusive evidence that various agents which have been pro-

posed as stimulants of leukocyte recovery, including one which was at one time very popular, Pent-nucleotide, are of any value. Before the sulfonamides and penicillin were available, the prognosis was very poor. Mortality was as high as 70 to 90 per cent. With modern chemotherapy, only a small proportion of patients fail to recover. During recovery, with the reappearance of leukocytes, abscesses may develop which will require appropriate therapy.

Splenectomy has been associated with considerable improvement or even recovery in some cases of the chronic, recurrent, and cyclic varieties, but this result is unpredictable. The steroid hormones may be of temporary value, perhaps in the cases most likely to respond to splenectomy, but they are difficult to evaluate in disorders of this type. In the chronic cases with *hypoplastic* bone marrow, splenectomy has not been found to be helpful.

THE PANCYTOPENIAS

Definition. The term *pancytopenia* refers to a reduction in the number of all three formed elements of the blood: the red corpuscles, the leukocytes, and the platelets. This is not a disease entity but a triad which is encountered under a widely differing group of circumstances.

Classification. This triad may be encountered in "aplastic" or "hypoplastic" anemia, in "aleukemic" or subleukemic leukemia, in myelosclerosis and in myelophthisic anemias, in pernicious anemia, and in association with a number of disorders of the spleen (Table 240-2). Under this heading "ag-nogenic myeloid metaplasia" and "primary splenic panhematopenia" must also be considered.

Aplastic Anemia

This term, in its strict sense, refers to a condition in which signs of hematopoiesis are lacking in the bone marrow, fat having replaced the blood-forming tissue. At the same time, there are anemia, granulocytopenia, and thrombocytopenia. There are no signs of blood regeneration. The reticulocyte count is very low or zero, there is no polychromatophilia or basophilic stippling, and nucleated red corpuscles and immature leukocytes of all types are absent. The anemia is usually normocytic, sometimes macrocytic; the red corpuscles vary little in size and not at all in shape. Bleeding time is usually moderately prolonged, the clot retracts poorly, and the tourniquet test is positive. Coagulation time is normal.

The onset of the disorder is insidious. The symptoms may be those attributable to anemia, or the effects of thrombocytopenia or of granulocytopenia may dominate the clinical picture. There is striking, often "waxy" pallor, but weight loss is unusual.

Table 240-2. CAUSES OF PANCYTOPENIA

- I. "Aleukemic," leukopenic, or subleukemic leukemia
- II. "Primary" refractory anemias
 - A. Aplastic anemias due to chemical or physical agents
 - B. "Idiopathic" aplastic anemia, including the familial type ("Fanconi syndrome")
- III. Myelophthisic anemias
 - A. Metastatic carcinoma in bone marrow
 - B. Multiple myeloma
 - C. Myelofibrosis, "ag-nogenic myeloid metaplasia," etc.
 - D. Marble bone disease (osteopetrosis)
- IV. Disorders involving the spleen—"hypersplenism"
 - A. Congestive splenomegaly
 - B. Lymph node disorders: lymphosarcoma, reticulum cell sarcoma, Hodgkin's disease, giant follicular lymphoma
 - C. Infiltrative disorders: Gaucher's disease, Niemann-Pick disease, Letterer-Siwe disease
 - D. Infectious diseases: kala-azar, miliary tuberculosis, sarcoid, syphilis
 - E. "Primary splenic panhematopenia"
- V. Deficiency anemias: pernicious anemia and other megaloblastic macrocytic anemias
- VI. Paroxysmal nocturnal hemoglobinuria (rarely)

SOURCE: Adapted from M. M. Wintrobe: "Clinical Hematology," 5th ed., Philadelphia, Lea & Febiger, 1961.

There may be bleeding from the nose, mouth, vagina, or elsewhere. Hemorrhages may be found in the eye grounds or skin. Ulceration in the mouth and pharynx or other evidence of infection may be encountered. There is no sternal tenderness, splenomegaly, or hepatomegaly, and lymph node enlargement, if present, is found only in relation to local infection.

This picture may follow exposure to a variety of *chemical and physical agents*. As with the causes of granulocytopenia, the agents associated with the occurrence of aplastic anemia may be divided into two groups; viz., (1) those which regularly produce marrow hypoplasia and aplasia if a sufficient dose is given, and (2) those which are only occasionally associated with such a change and presumably depend on idiosyncrasy. In the former category may be included ionizing radiation (roentgen rays, radioactive phosphorus, etc.), the mustards (sulfur and nitrogen mustards, TEM, etc.), urethan, busulfan, benzol, and the antimetabolites (antifolic acid compounds, 6-mercaptopurine, etc.). It will be noted that these agents have been or are used in the treatment of leukemia, Hodgkin's disease, and related disorders. Excessive dosage will result in the production of marrow aplasia. Benzene (benzol) is no longer used in the treatment of leukemia, but it is employed in many industries (leather, enamel, rubber, lacquer, electroplating, airplanes, linoleum,

celluloid, etc.) and must thus be kept in mind when aplastic anemia is encountered in a person working in one of these industries. Of the agents occasionally associated with hypoplasia or aplasia of the bone marrow, the following should be mentioned in particular: antimicrobial agents (arsenobenzols, chloramphenicol), anticonvulsants (Mesantoin), antithyroid drugs, antihistamines, insecticides, and various miscellaneous agents such as gold preparations and trinitrotoluene. Although the evidence incriminating these drugs is only circumstantial, a sufficient number of cases have been reported to make it seem very likely that development of aplastic anemia following exposure to the drugs named is more than a coincidence. Less convincing is the evidence that other drugs are the cause of aplastic anemia, since there are only single or very few reports incriminating them. In this last group may be mentioned the sulfonamides, oxytetracycline, chlortetracycline, Tridione, Nuvarone, Carbinazole, Tapazole, quinacrine, phenylbutazone, chlorpromazine, and various hair dyes and volatile insecticides.

"Idiopathic" cases have also been described in which exposure to an offending agent could not be discovered. Such cases have been observed most frequently in young adults or adolescents. Still another form of pancytopenia with hypoplastic bone marrow has been observed, usually at an even younger age, which may be familial and is associated with a variety of congenital defects (bone abnormalities, particularly of the forearms and thumbs, microcephaly, hypogenitalia, genitourinary tract abnormalities) and a generalized olive-brown pigmentation of the skin (Fanconi syndrome).

In addition to such cases of classic aplastic anemia, a very similar clinical and hematologic picture can be observed together with cellular or even hyperplastic bone marrow. In still other cases little or no reduction was present in the leukocyte or platelet count. Such pure erythrocyte hypoplasia has been observed as a congenital disorder, but rarely it appears also to be acquired. In a number of cases benign thymoma was associated. In some cases occasional nucleated red corpuscles, polychromatophilia, stippling, and immature white cells have been found in the blood, and splenic and hepatic enlargement and even general lymphadenopathy have been described. Whether all these cases should be classed with the true aplastic anemias under one category of "refractory anemias" cannot be settled until their pathogenesis is clear. That these various pictures may be variants of the same fundamental process is suggested by the observation that benzene poisoning not only may produce aplastic anemia but also can be associated with a regenerative blood picture, including even a leukemoid reaction, and the bone marrow may be hyperplastic rather than

acellular. Again, internal irradiation produced by the ingestion of radium by watch-dial workers was found to be characterized by macrocytic anemia with nucleated red corpuscles in the blood, and bone marrow with primitive red corpuscle and leukocyte hyperplasia.

Under the title of "sideroblastic" refractory anemias still another group of cases has been recognized which must be distinguished from "idiopathic" aplastic anemia and can be separated from thalassemia and the hemoglobinopathies (Chap. 235), from pyridoxine-responsive anemia, and from inclusion body anemias. Anemia refractory to all known forms of therapy, hyperplastic bone marrow, and signs of impaired iron utilization (sideroblasts, hemosiderosis) characterize these cases. Some appear to have begun in childhood, others have appeared in older patients. Their nature awaits clarification.

Myelophthisic Anemia

This term is applied to the type of anemia associated with space-occupying disorders of the bone marrow. Metastatic carcinoma (e.g., that arising from malignancy of the breast, prostate, lung, kidney, adrenal or thyroid gland), leukemia, multiple myeloma, and a disorder known as myelofibrosis or myelosclerosis are conditions which produce myelophthisic anemia. In *myelofibrosis* there is an irregular increase of fibrous or bony tissue in the bone marrow which is often associated with progressive anemia. The outstanding symptom is splenomegaly. The course is very slow. Bone marrow involvement may also occur in Hodgkin's disease and in the primary xanthomatosis (Gaucher's disease, Niemann-Pick disease, Schüller-Christian disease).

Agnogenic Myeloid Metaplasia

The term agnogenic myeloid metaplasia has been applied to cases in which the spleen showed marked myeloid metaplasia, apparently as the result of a compensatory reaction. This does not seem to be a disease entity. The bone marrow has been variously fibrotic, hyperplastic, aplastic, or normal. The blood picture has varied, like that described under Myelophthisic Anemia above. In some cases jaundice was present. In a number of instances a history of exposure to certain industrial solvents, including benzene and carbon tetrachloride, was obtained.

Primary Splenic Panhematopenia

Primary splenic panhematopenia is the term which has been applied to cases associated with splenomegaly in which all three formed elements of the blood have been reduced in number, and where excessive phagocytosis of these elements by the splenic macrophages has been conceived as being

the fundamental disorder. Splenectomy is described as producing dramatic improvement. In these cases little or no evidence of increased blood destruction has been observed, the reticulocyte percentage has been slightly or greatly increased, polychromatophilia has been noted, and the bone marrow picture has been one of hyperplasia. As will be pointed out in the next section, many splenic disorders are accompanied by pancytopenia.

Diagnosis and Treatment. It is evident from this outline that pancytopenia may be due to a number of causes of greatly varying nature. The recognition of the underlying disorder will depend on thorough study, which includes a painstaking history with careful inquiry about possible exposure to toxic agents, thorough physical examination and bone marrow examination, in addition to a complete survey of the blood.

While the blood picture in these conditions may be that of a pancytopenia and may appear "aplastic," as described above, it is necessary to stress that this is not always the case. Anemia is variable in degree. It may be normocytic or macrocytic, and nucleated red corpuscles may be seen in the blood even when there is little anemia. Reticulocytes may be increased and polychromatophilia and stippling, as well as "teardrop" poikilocytes, may be present. Such poikilocytes have been thought to be characteristic of myelofibrosis. The leukocyte count may be normal, reduced, or increased. If there is leukopenia there may be a uniform reduction in all the cells. The blood may contain myelocytes and myeloblasts. The platelet count may be normal or moderately reduced.

However, bone marrow punctures in various sites (sternum, pelvic crest, spinous processes) may be required before tumor cells are discovered. Roentgenograms, especially of the bones, may be helpful, and trephine biopsy of the marrow may be necessary. If an enlarged lymph node is accessible, it may be advisable to examine this microscopically, and other procedures may need to be carried out in the search for malignancy. A diagnosis of "idiopathic" aplastic anemia or of "primary splenic panhematopenia" should be one of exclusion.

Treatment will depend on the nature of the underlying disorder. Blood transfusions are of temporary value in all the conditions which may produce this picture. Ultimately, if many transfusions are given, hemochromatosis is produced, since the iron from the transfused cells cannot be excreted. Liver extract, vitamin B₁₂, folic acid, and iron are of no value. The temptation to remove an enlarged spleen must be tempered with good judgment. This is especially important in those cases in which the spleen has assumed the function of the bone marrow, for in such cases splenectomy can be harmful and at least is often of little or no value. Neverthe-

less, occasional patients derive definite benefit from splenectomy, particularly when there is severe thrombocytopenia or increased blood destruction. In cases in which large numbers of leukocytes in the circulating blood have been present, roentgen therapy or chemotherapy such as that used in the treatment of chronic leukemia has been helpful.

241 THE LEUKEMIAS

M. M. Wintrobe

Definition. Leukemia, probably a neoplastic disease, is characterized by widespread and abnormal proliferation of the leukocytes and their precursors throughout the body, particularly in the bone marrow, spleen, and lymph nodes. There are various types of leukemia, differentiated mainly according to the predominant abnormal cell forms. The morbidity of the process ranges from an acute disorder of but a few weeks' duration to a chronic one compatible with life even for many years. The termination, however, is always fatal.

History. Knowledge of leukemia can be traced back to the period from 1839 to 1845 when Donné made the first microscopic observations and Craigie, Bennett, and Virchow distinguished the clinical entity. Virchow recognized the cells as being leukocytes, not pus cells, and distinguished a lymphatic and a splenic type of leukemia. With the development of Ehrlich's blood-staining methods in 1891, Neumann's myelogenous form was recognized as being the same as Virchow's splenomegalic type. Acute leukemia was recognized by von Friedreich in 1857 and by Ebstein in 1889, and the myeloblastic form was separated from the lymphoblastic type when Naegeli described the myeloblast in 1900. Reschad and Schilling-Torgau described monocytic leukemia in 1913. Since then variations from the classic pictures have been recognized and methods for palliative management have been developed, but little advance has been made in gaining an understanding of the actual cause of this invariably fatal process, or in its prevention or specific treatment.

Varieties of Leukemia and Incidence of Various Types. Acute and chronic forms of leukemia can be distinguished on clinical grounds as well as on the basis of the predominant abnormal cell types. Without treatment, acute leukemia usually is fatal within 6 months; the duration of life in chronic leukemia may be several years—usually 3 to 5, sometimes 1 or 2, and in other cases 10 or more. "Subacute" leukemia is not truly intermediate between acute and chronic leukemia. The course and the clinical and hematologic pictures resemble those

of the acute form, but the progress of the disease is slower than in acute leukemia. Since myeloblasts, lymphoblasts, myelocytes, lymphocytes, or monocytes are the predominant cells in the great majority of cases of leukemia, the terms *acute* or *chronic* (and, if one wishes, *subacute*), qualified by the name of the predominant cell type, appear to be the most satisfactory designations for the different varieties of leukemia.

Leukocytosis is found in the majority of cases of leukemia. "Aleukemic" or, more correctly, sub-leukemic leukemia refers to cases in which leukocytosis is absent. Such cases are more often acute than chronic.

Leukemia is as common a cause of death as diphtheria or measles. Deaths from leukemia represent about 3.6 per cent of those due to cancer. There was a steady increase in the number of deaths from leukemia until 1940 or 1950 but the rate of increase has declined since then. Contrary to earlier statistics, it appears now that the proportions of cases of chronic myelocytic and chronic lymphocytic leukemia are approximately equal. Chronic leukemia is perhaps twice as common as the acute variety. The incidence of the various types of acute leukemia, including monocytic leukemia, is difficult to determine because conclusions must necessarily be influenced by differences in interpretation of the cell morphology. In various series, 11 to 21 per cent of the cases were subleukemic.

Etiology and Pathogenesis. While any variety of leukemia may occur at any age, it is nevertheless true that acute leukemia is much more common before the age of twenty-five than later, and is especially frequent under five years of age; chronic myelocytic leukemia has its highest incidence between the ages of twenty-five and forty-five, and chronic lymphocytic leukemia is seen especially after the age of forty-five or fifty. A difference in the sex incidence of leukemia becomes perceptible as age advances, there being essentially no difference in the occurrence of acute leukemia in male and female children and young adults, a slight preponderance of chronic myelocytic leukemia in males, and a distinct preponderance of chronic lymphocytic leukemia in males (3:1).

On the basis of past experience it can be stated that the probability that leukemia will occur more than once in a family is very small. This seems strange when one considers that susceptibility to experimental leukemia and the transmission of the spontaneous disease in experimental animals follow definite genetic laws. The explanation probably lies in the fact that, although hereditary factors do exert an influence on the etiology of human leukemia, as exemplified by familial cases of chronic lymphocytic leukemia especially, their effect is modified by external influences and by other genes. External fac-

tors include the effects of irradiation and perhaps also of chemical agents and of trauma. Leukemia has been described so much more often in persons exposed to radiation (such as roentgenologists and those who were exposed to the atom bomb in Japan as well as in patients with ankylosing spondylitis who received roentgen therapy) than in those not so exposed that this agent cannot be overlooked in a consideration of etiologic factors. Not so well documented, but nevertheless deserving serious consideration, as causes of leukemia are trauma, especially to bones, and exposure to certain chemical agents, especially benzol.

The febrile character of acute leukemia and the evidences of infection, about the mouth especially, which can be seen in many cases have led some to hold the opinion that the disease is caused by an infectious agent. Such a concept is difficult to accept, as none of the other customary evidences of infection has been observed, such as transmission from man to man or from mother to fetus. Experimental fowl leukemia, it is true, is carried by a filtrable agent, but this is so also with certain other types of neoplasms. Newer knowledge is developing concerning the existence of transmissible cytoplasmic agents which determine the character of cells. The role of viral agents in the etiology of human leukemia is under active investigation.

The essential change in this disease is thought to reside in the leukemic cell and is believed to consist of an acquired inability of these leukocytes to respond to forces which normally regulate their proliferation and maturation. The end result is a new type of cell with certain fixed abnormalities in appearance and behavior. Peculiarities have been observed in leukemic cells which are like those of neoplastic cells, including abnormal size and number of nucleoli and atypical as well as abnormal mitoses. In some leukemic leukocytes chromosomal changes have been observed. The causes of this change may be manifold; perhaps in a given case the development of the disease depends on the interplay of a variety of factors, including genetic constitution and external influences, such as irradiation, chemical agents, and cytoplasmic particles.

Pathology. The fundamental change in leukemia is widespread proliferation in the tissues, and usually also in the blood stream, of cells of a particular type. In chronic myelocytic leukemia the bone marrow and spleen are chiefly involved, but the lymph nodes, liver, kidneys, lungs, skin, and other organs are also infiltrated. The splenic pulp is full of myeloid cells, and infarcts are commonly present. In the chronic lymphocytic variety the lymphoid organs in particular show striking hyperplasia with disturbance of architecture, and the liver, bone marrow, and other tissues are affected as well. In acute leukemia the changes are similar and are ac-

companied by evidences of hemorrhage, the result of the accompanying thrombocytopenia.

Clinical Manifestations. The clinical manifestations of the chronic and the acute leukemias differ from one another a great deal, but there is comparatively little difference in the symptomatology of the various types of chronic leukemia, and essentially no difference in the clinical pictures of the different forms of acute leukemia.

Chronic Myelocytic Leukemia. The onset is insidious, and complaints may not develop until the disease has been in progress for a long time, perhaps a year or two. The most common symptoms are those of anemia (weakness, pallor, palpitation, or dyspnea); or a dragging sensation or swelling in the left side of the abdomen, due to the splenic enlargement; or complaints attributable to the increased metabolic rate which develops as the disease progresses (loss of weight, weakness, nervousness, cachexia, etc.). There may be slight fever, rising as high as 101°F, rarely higher. As the disease advances, the clinical picture may become more "acute" in that chills and fever may develop, weight loss may become excessive, and an abnormal tendency to bleed may become manifest.

The appearance of the patient ranges from that of seeming perfect health to one of extreme cachexia with marked pallor. Splenomegaly is often the first physical sign of the disease. The spleen may be just palpable or it may be huge, the abdomen, protuberant from this cause, standing out in striking contrast to the general emaciation. Lymph node enlargement is rarely significant, but tenderness, elicited on pressure over the lower portion of the sternum, is a moderately early sign.

Other symptoms and signs are less common, but any system of the body can be affected. The liver is often enlarged, sometimes greatly, and, like the spleen, is firm and not tender. The skin may show small, bluish-gray, elevated nodules, due to specific infiltration. The retinas may show hemorrhages and leukemic infiltrations. There may be subperiosteal infiltration and even destructive lesions of bone leading to pathologic fractures. Deafness, from infiltration in the middle or inner ears, or from hemorrhage; evidences of nervous system involvement due to the same causes, hematuria in association with infiltration of the kidney; or other still less common manifestations may be observed. Pain may develop from perisplenitis, or in some cases pleural effusion may occur.

The blood picture depends on the stage of the disease. The earliest manifestation is leukocytosis, due to an increase in the myeloid series of cells. Early in the disease the "shift to the left" is usually orderly with fewer metamyelocytes than segmented neutrophils, fewer myelocytes than older forms, and often few or no myeloblasts. Later the myelocytes,

PLATE II

(Top) Acute leukopenic myelogenous leukemia. (WBC 3,000.) Film from buffy coat. Actual field. Five myeloblasts, several showing nucleoli. (Lower left) Promyelocyte. Three nonsegmented neutrophils, practically destitute of granules (toxic-degenerative changes). (Lower right) Two megakaryocyte nuclei with shreds of platelet material attached. (Bottom) Cells from case of acute monocytic leukemia. (1 to 14) Monocytes. (1 and 3) Monoblasts. (Stitt, Clough, and Branham: "Practical Bacteriology, Hematology, and Parasitology," 10th ed., New York, The Blakiston Division, McGraw-Hill Book Company, Inc., 1952.)

including the earlier forms, tend to dominate the picture, especially in the most advanced and more "acute" stages. Eosinophils and basophilic leukocytes are likely to be found, sometimes in substantial numbers. If they are very numerous, the terms *eosinophilic leukemia* and *basophilic leukemia* are appropriate. The leukocyte count most often ranges between 100,000 and 500,000 cells per cu mm when the disease is first discovered, but values as great as 1,000,000 are sometimes seen. Monocytes are present in normal or slightly increased numbers, whereas lymphocytes, though reduced in percentage, maintain about a normal absolute value.

The degree of anemia is a good index of the extent of the leukemic process. In the earliest stages there is no anemia; in far advanced cases it is profound. The manner in which anemia is relieved when therapy reduces the extent of myeloid infiltration or becomes more severe as the disease advances gives support to the view that its cause is related to encroachment on the erythrocyte-forming elements by the leukemic cells. The anemia is usually normocytic in type. A few normoblasts are likely to be seen in the blood smear, as well as slight polychromatophilia and occasional stippling.

The platelets are normal in number or increased, except in the terminal stages of the disease when infiltration is extensive. Then hemorrhagic manifestations, prolonged bleeding time, and other signs of secondary thrombocytopenic purpura are found. In rare cases the platelet count may be extremely high, and even megakaryocytes or fragments thereof may be found in the circulating blood.

Chronic Lymphocytic Leukemia. The onset is insidious, as in the myelocytic form, but the first symptom is likely to be painless enlargement of lymph nodes in the neck, axilla, or groin. In other instances manifestations of anemia may dominate the picture, and less commonly splenic enlargement or hemorrhagic manifestations may be the presenting complaints. The skin is more often involved in the lymphocytic form than in the myelocytic, as are also the gastrointestinal tract and the mediastinum. There may be itching and burning, with yellowish-brown, red, bluish-red, or purple, nodular skin lesions. Bone tenderness is less frequent than in myelocytic leukemia. The lymph nodes vary in size from that of a pea to that of a hen's egg; though they are discrete, several lying together may produce a huge mass. They are moderately firm and smooth. Other manifestations are similar to those encountered in chronic myelocytic leukemia.

The blood picture is that of a monotonous collection of small lymphocytes each looking just like its fellow, contrasting strikingly with the colorful picture of myelocytic leukemia. The leukocyte count more often ranges between 50,000 and 250,000 per cu mm than at higher levels, and 90

per cent or more of these cells are lymphocytes. They often possess only a narrow rim of cytoplasm and may even appear to have none. Larger lymphocytes may be seen, but true "blast" forms with clearly defined nucleoli are unusual.

As in myelocytic leukemia, the presence or absence of anemia and its degree are good indexes of the extent of infiltration. The anemia is normocytic, and there may be occasional immature red cell forms in the blood smear. Early, the platelet count is normal; as the disease advances, it becomes greatly reduced and hemorrhagic manifestations may develop.

Acute Leukemia. The onset of acute leukemia is frequently rather abrupt, and, depending on the location and nature of the initial disturbance, a great variety of clinical pictures may be encountered. The initial symptoms may arise from leukemic infiltrations and glandular enlargement, from hemorrhages, or as the result of the systemic effects of the disease, including those associated with anemia. Sore throat, abnormal bleeding from the mucous membranes or petechiae or ecchymoses in the skin, cough or dyspnea resulting from enlargement of the thymus or mediastinal lymph nodes, rheumatoid pains, and a variety of neurologic complaints are among the manifestations which may be encountered. Excessive bleeding following the extracting of a tooth or from minor injuries may be the first evidence of the disease. Fever, headache, and general malaise may be soon followed by marked prostration, and the onset of some severe, malignantly virulent form of sepsis may be suspected.

Lymph node enlargement is usually less conspicuous than in chronic leukemia, but a systematic search will frequently reveal more or less generalized involvement of the lymph nodes. The spleen is usually palpable but is rarely very large. The liver is often enlarged. The gums may be swollen and purplish in color, and there may be ulceration in the mouth. Sternal tenderness is present in the great majority of cases.

Differentiation of the various types of acute leukemia cannot be made on clinical grounds and is often difficult even from the blood examination. Anemia is practically always present when the disease is first discovered; often it is severe. The anemia is usually normocytic, sometimes macrocytic. Polychromatophilia, as well as normoblasts, are often found. The platelet count is usually decreased, at least to some degree, even when the disease is first discovered. The bleeding time then is prolonged, the clot retracts poorly, and the tourniquet test is positive.

The leukocyte count rarely attains levels higher than 100,000 per cu mm; not infrequently it is below normal, even below 1,000. At first glance the predominant cells are likely to be mistaken for

lymphocytes. Well-stained, thin smears are needed to demonstrate that the cells are abnormal and contain nucleoli. When they are lymphoblasts or myeloblasts or even more immature forms (stem cells) they are difficult to distinguish from one another. The nuclear differences are not easily recognized even by those with considerable experience, and their cytoplasm is scanty and nongranular. However, in *acute myeloblastic leukemia* a small proportion of cells of slightly later development will often be found which will be seen to contain peroxidase-positive granules. Since such cells are lacking in *acute lymphoblastic leukemia*, differentiation can sometimes be made on this basis. *Acute monocytic leukemia* can be distinguished more easily, however. The "pure" and rarer form, the *Schilling type*, is characterized by the presence of large cells with lacy chromatin, irregular nuclei, inconspicuous nucleoli, and irregular cell borders. The cytoplasm contains innumerable very fine, dustlike granules. At the same time a few nongranular, "blastlike" cells with nucleoli are found, probably "monoblasts." In the *Naegeli type* of monocytic leukemia, myelocytes are found in relatively large numbers, in addition to cells resembling monocytes.

Less Common Types of Leukemia. **SUBLEUKEMIC (ALEUKEMIC) LEUKEMIA.** This term refers to leukemia of any type in which the leukocyte count is only slightly elevated, normal, or less than normal. In such cases the abnormal cells may not predominate in the blood smear, in fact, they may be scarce and may not be readily discovered. In most instances in which leukemic cells are stated to be absent, however, a good smear and stain and careful scrutiny by a person with some experience will usually reveal at least a few. In any event, the bone marrow contains a large number of the abnormal cells, although sometimes they may be held together so firmly that they are not readily aspirated. A normal or subnormal leukocyte count may be encountered at some stage of chronic or acute leukemia, especially the latter. This may be followed by a phase of leukocytosis or, more often, leukocytosis may be only a terminal event. Sometimes leukocytosis never develops.

CHLOROMA. This term refers to a variant of acute leukemia which is characterized by the presence of greenish localized tumors, connected particularly with the periosteum and ligamentous structures of the skull, paranasal sinuses, orbits, spine, ribs, and sacrum. Protrusion of an eyeball, with diplopia and loss of vision, pain, deafness, and signs of various cranial nerve palsies, or other effects of pressure or infiltrative growth in a case otherwise consistent with a diagnosis of acute myeloblastic leukemia should lead to suspicion of chloroma.

CHRONIC MONOCYTIC LEUKEMIA. The great majority of cases of monocytic leukemia are acute or sub-

acute, as already described. A small number are slower in their course. Relatively low or subnormal leukocyte counts, bone pain, and cutaneous manifestations have characterized these cases.

LYMPHOSARCOMA CELL LEUKEMIA. The "lymphosarcoma cell" is about 9 to 14 μ in diameter, has a sparse but deeply basophilic cytoplasm, an oval, oblong, or kidney-shaped nucleus with coarsely reticular, spongy chromatin, and a single, prominent nucleolus. Such cells are seen in cases fitting the category of "leukosarcoma," proposed by Sternberg. Enlargement of lymph nodes in any one of many sites, but especially in the anterior mediastinum, or symptoms referable to anemia, may for months or even years precede the appearance of these cells in the blood. The leukocyte count may remain normal or low for a long time or even throughout the illness, even though 30 to 98 per cent of the cells may ultimately be of the lymphosarcoma cell type.

PLASMA CELL LEUKEMIA. This term is applied to rare cases in which plasma cells have been found in the blood but which in other respects resemble leukemia—i.e., there are leukocytosis, anemia, and splenic and frequently lymph node and hepatic enlargement. This disorder is perhaps but a variant of plasma cell myeloma, but in contrast to typical multiple myeloma (Chap. 244), bone involvement and hyperproteinemia may not be present. There may be extraosseous plasmacytomas in the upper respiratory passages, the cornea, the pleura, and elsewhere.

A number of other, still more rare forms of leukemia have been described. They include so-called "megakaryocytic" and "acute megakaryoblastic" leukemia, eosinophilic leukemia, and basophilic, or mast cell, leukemia. The clinical course of some cases of eosinophilic leukemia is so unlike that of monocytic leukemia that in some instances one wonders whether they represent true leukemia. *Acute and chronic erythremic myelosis* (di Guglielmo syndrome) refers to a disorder in which the erythropoietic tissue, rather than the leukopoietic tissue, seems to be involved in a neoplastic process. The blood contains numerous erythroblasts in all stages of maturation, but the most immature forms are found in disproportionately large numbers. Other manifestations are similar to those seen in leukemia. The term *erythroleukemia* refers to a very rare disorder in which there appears to be a combined neoplastic hyperplasia of both erythroblastic and leukoblastic tissues. Cases such as these and lymphosarcoma cell leukemia, plasma cell leukemia, and cases of lymphocytic leukemia with only minor changes in the blood give support to the view, now widely held, that these conditions and those chiefly affecting lymph nodes, such as lymphosarcoma, as well as multiple myeloma, are very

closely related disorders or simply variations of a single abnormal process.

Diagnosis. The diagnosis of leukemia is not difficult in most cases. Confusion may arise when the blood has not been examined thoroughly, when the question of a leukemoid reaction arises, or when the blood is subleukemic.

Instances of chronic leukemia, because of lymph node or splenic enlargement, may suggest one of the various disorders affecting lymph nodes or the spleen (Chaps. 242 and 243), or if the chief symptoms draw attention to other systems of the body, a very great variety of conditions may be simulated. Acute leukemia, as already mentioned, may suggest acute inflammatory conditions of various kinds, purpura hemorrhagica, or other disorders.

Hematopoietic responses which suggest leukemia (*leukemoid pictures*) may be observed under a variety of circumstances:

1. In association with *infections*. A picture resembling myelogenous leukemia is sometimes associated with pneumococcal and meningococcal infections and rarely is seen in diphtheria and tuberculosis. Lymphocytic leukemia may be suggested by the leukocytic reaction in whooping cough, infectious mononucleosis, and infectious lymphocytosis, in particular, and sometimes in chickenpox.

2. *Intoxications*. In rare instances of eclampsia, severe burns, diabetic acidosis, and mercury poisoning, leukemoid pictures have been observed.

3. *Malignancy*, especially with bone metastases, as well as in multiple myeloma, myelosclerosis, and Hodgkin's disease.

4. Following *severe hemorrhage or the rapid destruction of blood*, when the profound stimulus to the bone marrow may bring forth a marked leukocytosis as well as immature forms of the nucleated red corpuscle series.

The essential findings in the blood which favor leukemia rather than a leukemoid reaction are (1) pronounced immaturity of the leukocytes, which is more significant than their number; and (2) evidence of other hematopoietic disturbances, which includes (a) anemia; (b) the presence of immature red corpuscle forms in the blood, such as nucleated red corpuscles and polychromatophils; and (c) platelet abnormalities, especially thrombocytopenia. Only in the early stages of chronic leukemia are anemia and other signs of disturbed hematopoiesis lacking. In leukemia the immaturity of the leukocytes often is not orderly as in the case of a physiologic response, where there are successively fewer numbers of the various immature forms, with at most but a small number of myelocytes and but 1 or 2 per cent of myeloblasts.

These criteria usually suffice to distinguish leukemia from a leukemoid reaction. In addition, the clinical findings, such as splenomegaly, lymphad-

enopathy, and sternal tenderness, make it apparent that one is dealing with leukemia. On rare occasions, however, differentiation is quite difficult, for the disease simulating leukemia may be accompanied by some of these physical signs, and even immature forms of the red corpuscle series may find their way into the blood.

In subleukemic leukemia especially, and in the less clear instances where leukocytosis is present, the bone marrow examination is very helpful, for there abnormalities will usually be found which are well beyond the normal variations. Only in the early stages of chronic lymphocytic leukemia or in the rare cases in which the marrow involvement is not diffuse, is the sternal puncture likely to be disappointing. In chronic myelocytic leukemia the cells in the bone marrow may be at a slightly less mature level than in the blood. In acute myeloblastic leukemia, even when there are few immature forms in the blood, the marrow is crowded with myeloblasts. In other types of acute leukemia the corresponding cells or their precursors will be found in large numbers in the marrow (see p. 213).

Other examinations which may be helpful in reaching a diagnosis include roentgenography of the bones, which may reveal superiosteal infiltration, osteolytic or tumorlike changes; measurement of the *basal metabolic rate*, which is increased in many cases of leukemia; and sometimes lymph node biopsy.

Course and Prognosis. With the possible exception of two or three instances, there are no authentic reports of cure of leukemia. In chronic leukemia the course is rarely interrupted by spontaneous remissions. In acute leukemia such remissions are observed occasionally, especially following infections, and may last for several weeks. The duration of life in cases of chronic leukemia varies greatly. In some, death ensues in a year or two after symptoms first appear; in others, the course may be extremely protracted, extending over 10 or 15 years and, very rarely, even longer. In certain cases such apparent long or short duration depends respectively upon early diagnosis or late discovery of the disease. In most instances the essential factor probably consists in different intensities of the pathologic process. The average duration of life in chronic myelocytic leukemia is 3.2 years; in the lymphocytic variety, 5.4 years. It is thought that about 20 per cent of patients survive more than 5 years. For acute leukemia, available statistics vary, but in the largest series which has been studied, the mean survival time from the onset of symptoms was 4.7 months in patients treated only with transfusions and antibiotics. The longest was 56 weeks, but 50 per cent of the patients were dead within 17 weeks, 90 per cent within 36 weeks.

In chronic leukemia, treatment, even though it

may not increase survival time by more than 6 months or a year, can for much of the time make the difference between a state of chronic invalidism and a condition of well-being which may approach normality. In acute leukemia the newer methods of treatment have made it possible in many instances to bring about and maintain remission in children for significant periods of time and perhaps also to prolong life. In adults the results of treatment in most cases have been much less satisfactory.

Prognosis in chronic leukemia can be judged more from the degree of anemia and the extent of weight loss than from the magnitude of the leukocyte count, especially if these fail to respond following therapy. Thrombocytopenia is also an unfavorable sign, for, except in occasional cases of chronic myelocytic leukemia, this indicates extensive infiltration of a degree not likely to be greatly influenced by treatment.

Treatment. Although cure of leukemia has not been achieved as yet, present-day methods of therapy provide considerable improvement, reduce morbidity, and may even prolong life, as outlined above. In addition to irradiation and chemotherapy, which will be considered below, *general measures of management* are important. These include blood transfusions, when necessary, and antibiotics. The latter are often not needed if only leukopenia is present; they are better reserved for prompt use at the first sign of infection. Good oral hygiene is important, as well as a well-balanced, nourishing diet. Advice concerning rest and activity should be guided by the make-up of the patient. In general, patients with leukemia should be encouraged to maintain their normal activities in so far as possible, treatment should be provided with the object of reducing morbidity, and hospitalization should be reduced to a minimum.

Irradiation. This is of value in chronic leukemia and may be given by means of roentgen rays, radioactive phosphorus (P^{32}), radium, thorium X, or mesothorium. Only the first two are now used. Increasing anemia, loss of weight, pressure symptoms, invasion of tissues with production of pain, or disfiguring or uncomfortable glandular enlargement are indications for treatment. These are of more importance than a high or rising leukocyte count. While hemorrhagic manifestations and thrombocytopenia, like anemia, may be due to marrow infiltration by leukemic cells and thus may be alleviated by treatment, more often they are part of the terminal picture of chronic leukemia and indicate that treatment is likely to be ineffective. Acute leukemia is another contraindication to irradiation. Such treatment is not only of little or no value but may be harmful.

Although roentgen therapy has been the gen-

erally accepted form of radiation therapy, the choice between this and treatment with P^{32} is mainly a matter of availability and convenience. The details of dosage are matters for the specialist. Serial daily doses of 100 to 200 r or as little as 25 to 50 r, appropriately filtered and over specified areas, are used by various workers. Treatment is stopped when the leukocyte count has fallen to approximately 25,000 per cu mm, but this is not an absolute criterion since irradiation, given cautiously, may prove effective even in cases with leukopenia.

Treatment with phosphorus made radioactive (P^{32}) offers the advantage that the radioactive material is concentrated in the position where it is especially required—that is, in those tissues which have a high phosphorus content and metabolize phosphorus rapidly: the liver, spleen, kidneys, and bone marrow. The material can be given orally or intravenously and, unlike roentgen irradiation, it does not result in radiation sickness.

There is good evidence that life can be prolonged with regularly spaced irradiation designed to keep the patient in a good state of health and at his normal occupation. There are few now who hold to the view that irradiation therapy, or chemotherapy for that matter, should be reserved for use only in well-established relapse or when symptoms are prominent.

Chemotherapy. Chemotherapy, besides being less expensive than roentgen-ray therapy as a rule, makes management practical for those patients who do not reside where roentgen therapy apparatus is available. Many roentgenologists employ daily treatments for 2 to 3 weeks, which may be inconvenient as well as expensive in some cases. A variety of chemotherapeutic agents is now available which can be taken orally. Observations on patients treated with such agents may be spaced at intervals of one to several weeks, thus permitting a return to normal activities and reducing cost. In the last analysis, however, treatment must be designed to suit the individual needs of the patient, and often both irradiation and chemotherapy are required at different times in the same person. Thus, disfiguring and uncomfortable adenopathy or great splenomegaly may call for local roentgen therapy, whereas systemic manifestations are well handled by chemotherapy or radioactive phosphorus.

In general, the chemotherapeutic agents useful in the treatment of chronic leukemia differ from those valuable in acute leukemia (Table 241-1).

CHRONIC LEUKEMIA. Chemotherapeutic agents include busulfan (a sulfonic acid ester, 1,4-dimethanesulfonyloxybutane), demecolcin (desacetyl-methylcolchicine), chlorambucil [p-(di-2-chloroethyl) aminophenylbutyric acid], and triethylenemelamine.

Table 241-1. RELATIVE VALUE OF DIFFERENT AGENTS IN TREATMENT OF LEUKEMIAS AND LYMPHOMAS

	Chronic leukemia		Acute leukemia			Hodgkin's disease	Lympho-sarcoma
	Myelo-cytic	Lympho-cytic	Myelo-blastic	Mono-blastic	Lympho-blastic		
Irradiation:							
Roentgen ray.....	++++	++++	0	0	0	++++	++++
Radioactive phosphorus.....	++++	+++	0	0	0	+	++
Chemotherapy:							
Nitrogen mustard.....	+	+	0	0	0	++++	++
Triethylenemelamine.....	+	++	0	0	0	++	+
Chlorambucil.....	+	+++	0	0	0	+++	++
Demecolcin.....	++	0	0	0	0	0	0
Busulfan.....	++++	+	0	0	0	0	0
Antifolic acid compounds.....	0	0	++	+	+++	0	0
Cortisone, prednisone.....	0	++	0	0	++++	+	++
6-Mercaptopurine.....	+	0	+++	++	+++	0	0

Although the nausea and vomiting associated with nitrogen mustard therapy (p. 1341) can be allayed considerably by sedatives or an antiemetic such as chlorpromazine, the discovery of other agents equally or more effective without such unpleasant action makes it unnecessary to use this drug. Similar to nitrogen mustard in pharmacologic effects is triethylenemelamine, which can be given orally and rarely causes gastrointestinal symptoms. This agent is a potent hematopoietic depressant and must be used with great caution. It is most useful in chronic lymphocytic leukemia. For the myelocytic variety other less toxic agents are available. Daily administration for a week or more seems unwise, since the depressant effect is cumulative. It is better to give the agent over a period of 1 to 3 days, waiting then for 2 or 3 weeks before more is given so that its full effect can be determined. As little as 1 or 2 mg may produce a fall in the leukocyte count and reduction in lymphadenopathy in chronic lymphocytic leukemia, but in other cases 5 mg and, rarely, even 10 mg may be required. The drug is usually given when the patient awakens in the morning together with 2 Gm sodium bicarbonate. Breakfast may be taken 2 hr later.

Even more useful in the treatment of chronic lymphocytic leukemia because it is somewhat less toxic is chlorambucil, an aromatic mustard. The usual dose is 0.1 mg/kg/day by mouth.

Busulfan (Myleran) is the most useful of the chemotherapeutic agents for chronic myelocytic leukemia. In oral doses of 4 to 6 mg daily, its use is associated with a reduction in the leukocyte count in the course of several weeks and a rise in hemoglobin, together with corresponding clinical improvement. Thrombocytopenia and purpura are the chief toxic manifestations, but these are uncommon.

Only rarely is there any gastric discomfort. When the leukocyte count has decreased to approximately 10,000 per cu mm, treatment is stopped. Remissions measured in months have been observed. Demecolcin (Colcemide, an alkaloid isolated from colchicum), also is effective in chronic myelocytic leukemia. The oral dose is 4 to 6 mg daily. However, relapse occurs promptly unless the drug is continued. Urethan is no longer used.

These agents, as already indicated, will bring symptomatic relief in many cases of chronic leukemia: lymph nodes will decrease in size, the spleen will become smaller, anemia will decrease or disappear, weight will be gained, and a sense of well-being will return, to remain for variable lengths of time. For the treatment of chronic lymphocytic leukemia, chlorambucil is perhaps the best of the chemotherapeutic agents available at present. For chronic myelocytic leukemia, busulfan is the most satisfactory drug, but demecolcin is sometimes effective when busulfan fails. They have little value in the lymphocytic form.

Splenectomy has been helpful in occasional cases of chronic lymphocytic leukemia when there was severe anemia associated with a reduced survival time of transfused red corpuscles, even in the absence of frank signs of hemolytic anemia. In such cases the steroid hormones, cortisone and prednisone, and adrenocorticotrophic hormone have also been useful, and they should therefore be given a trial before splenectomy is considered.

ACUTE LEUKEMIA. In acute leukemia, roentgen therapy is of no value, radioactive phosphorus has limited application, and the above-mentioned chemotherapeutic agents are of no benefit. Nitrogen mustard will reduce the leukocyte count and may relieve bone pain but offers nothing more. On the

other hand, the steroid hormones, the folic acid antagonists, and other agents, such as 6-mercaptopurine, are valuable in many cases.

The steroid hormones, of which *prednisone* and similar compounds are preferable since they can be administered by mouth, have been found to bring about a remission in at least two-thirds of the cases of acute lymphoblastic leukemia in children and perhaps in half this proportion of adults. To achieve these results, usually a dose must be given which is large enough to produce signs of hypercorticism, generally 40 mg prednisone daily. Such treatment rarely needs to be supplemented by potassium chloride (2 to 6 Gm daily), and the diet need not be salt-free. A similar beneficial effect is rarely observed in myeloblastic or monocytic leukemia, in fact, these types may even be made worse. Once a remission has been attained, steroid therapy is stopped. The remission may last several weeks or sometimes months. One may attempt to prolong the remission by the administration of one of the antagonists. Re-treatment with steroid hormones may produce a second remission, but this is usually less complete than the first.

A variety of folic acid antagonists is available, but *amethopterin* (methotrexate, 4-amino-N¹⁰-methylpteroylglutamic acid) is more generally employed. The daily oral dose range of amethopterin is 1.25 to 5.0 mg, rarely more. The drug is given until a remission has been produced or severe toxic symptoms occur: oral ulceration, anorexia, nausea, vomiting and diarrhea, leukopenia, increasing thrombocytopenia and hemorrhage, and increasing anemia, alopecia, and skin rash. Sometimes it is very difficult to distinguish between toxic effects and an increase in the signs of leukemia. When given in large enough doses the antagonists will lead to the appearance of megakaryoblasts in the bone marrow. In children, with amethopterin as with steroids, remissions have been observed in approximately 60 per cent of those treated; in adults these agents are much less successful. Ultimately resistance develops in all cases and the drugs become no longer effective.

Of the other analogues of folic acid, purines, pyrimidines, and amino acids which have been studied with the object of discovering additional anti-leukemic agents, 6-mercaptopurine (6MP, Purine-thol) is the most clearly useful agent. Good clinical and hematologic remissions have been observed in somewhat less than 50 per cent of children with acute leukemia and in about 25 per cent of adults. Remissions have lasted from 1 to 10 months and have been observed even in patients who had become resistant to folic acid antagonists or to the steroids. The usual therapeutic dose is 2.5 mg per

this amount is given for a short time, but in such cases the danger of producing marrow hypoplasia must be kept in mind. This drug has also been found to produce improvement in early chronic myelocytic leukemia, and occasional beneficial effects have been observed in the terminal "acute" stage of chronic myelocytic leukemia. Such remissions, however, have usually been of short duration.

The most effective method for the treatment of acute leukemia is to use one agent at a time and to follow this with another one of the agents which has been shown to be effective. Thus, in the management of a case of acute lymphoblastic leukemia, one might initiate treatment with steroids, this being continued until a remission has been produced. Therapy is then interrupted, and the patient is observed at weekly or fortnightly intervals until the first suggestion of relapse appears. When beginning anemia, thrombocytopenia, fever, sternal tenderness, an occasional immature leukocyte in the blood, or any other evidence of beginning relapse appears, either a folic acid antagonist or 6MP is administered until a new remission has been achieved. If the remission is complete, treatment may be again interrupted and is resumed when evidence of relapse once again begins to appear, this time the third agent, either amethopterin or 6MP being used. Later still, any one of these agents may be tried again. By such a plan of alternating use of drugs, the development of "resistance" to one of these agents may possibly be delayed and it may be possible to prolong the life of the patient. In cases of acute myeloblastic or monocytic leukemia, the steroid hormones are of little or no value, as already mentioned, and treatment must depend on the antifolic acid compounds and 6MP.

A more common practice than the above method of interrupted therapy is to give maintenance therapy. Thus, when a remission has been brought about in a case of acute lymphoblastic leukemia with steroid therapy, usually after 5 to 6 weeks of such treatment, steroid administration is reduced and in the course of about 2 weeks it is stopped. Instead, 6MP is given, in doses of 2.5 mg per kg body weight per day. This is continued until signs of relapse, or of toxicity, appear. Remission may be maintained for many months in this way. If toxic symptoms develop, interruption of therapy for a week or two should suffice to eliminate them and treatment is then resumed, usually at a lower dose. When 6MP ultimately fails, a course of steroid therapy may be given again, to be followed by amethopterin maintenance therapy. Although it has not been proved that maintenance therapy permits longer survival than interrupted therapy, it is clear that long survivals can be achieved in this way. The use of a single agent at one time is important

¹ " body weight per day by mouth. Sometimes twice

not only because this permits other drugs to be held in reserve for use when relapse occurs but also because the interpretation of clinical and hematologic changes which occur during therapy is simpler and the differentiation of toxic effects from the signs of disease is easier.

Many other chemical compounds have been tested in the treatment of leukemia, but as yet none has been shown clearly to offer any advantages over the drugs discussed above.

Attempts to transplant human bone marrow in patients with leukemia who have been given heavy irradiation or chemotherapy with the object of destroying all the leukemic tissue have not met with success. The concept is intriguing but its value remains to be demonstrated.

242 DISEASES OF THE SPLEEN AND RETICULOENDOTHELIAL SYSTEM

M. M. Wintrobe

The functions of the spleen were outlined in an earlier chapter (p. 232). Disorders of the spleen most frequently produce enlargement of this organ. The significance of splenic enlargement has been considered already, and the differential diagnosis of splenomegaly was discussed there (p. 233). Here several of the disorders which involve the spleen, in particular, will be described.

Disorders of the spleen not hitherto considered include congenital anomalies, rupture, and infarction. *Congenital anomalies* may take various forms. Instead of being a single organ, the spleen may be subdivided into numerous small spleens, or a spleen of normal size and shape may be accompanied by one or more accessory spleens. Rarely, the spleen assumes a retroperitoneal position and may force the left kidney downward. A *movable* spleen may be found in any part of the abdomen. If its pedicle becomes twisted, there may be sudden pain, enlargement, and signs of shock, as well as fever and vomiting if the torsion has developed acutely. Less severe symptoms occur if the process is more gradual.

Rupture of the spleen may occur following trauma, particularly if the spleen is diseased. Malaria, typhoid fever, and infectious mononucleosis are among the diseases in which this has been observed. Agonizing abdominal pain or pain in the left scapular region, together with signs of internal hemorrhage, characterizes this catastrophe. Anemia develops rapidly and leukocytosis occurs. Prompt surgical treatment is imperative. After traumatic rupture autotransplantation of splenic tissue (*splenosis*) sometimes occurs.

Infarction of the spleen may be sterile, in which event it is followed eventually by fibrosis and shrinkage. This has been observed as a complication of leukemia. A septic infarct may terminate with the formation of an abscess. The most common symptom of infarction is pain. Careful examination will reveal a friction rub. Unless an abscess forms, necessitating surgical intervention, sedation and abdominal support to impair movement of the spleen suffice.

Congenital absence of the spleen may be suspected when Howell-Jolly bodies, occasional nucleated red cells, target cells, decreased osmotic fragility, siderocytosis, leukocytosis, and a variable degree of thrombocytosis are found in the absence of a discoverable cause and particularly when there

is associated congenital heart or intestinal malformation.

CHRONIC CONGESTIVE SPLENOMEGALY

Definition. This syndrome, also called *Banti's syndrome* or *splenic anemia*, is characterized by splenic enlargement, leukopenia, anemia and often thrombocytopenia, a tendency to gastric hemorrhage, and, in many cases, cirrhotic changes in the liver.

History. The term *splenic anemia* was originally used (1866) to refer to cases of anemia with splenomegaly which were not frank leukemia. Banti, in 1882 and subsequently, described a form of splenomegaly of unknown etiology associated in its earliest stages with leukopenia, asthenia, and occasional hemorrhagic episodes. In the intermediary stage, hepatic enlargement occurred, as well as urobilinuria and a dirty-brownish discoloration of the skin. The final stage consisted of liver atrophy and ascites.

Etiology. Banti described the spleen as being characterized by conspicuous thickening of the fibrillar reticulum in the Malpighian corpuscles and red pulp ("fibro-adenic"). These changes originated around the central artery of the follicle. In his opinion, the spleen was the primary seat of the disease. Later work showed that these changes are not specific and can be encountered particularly when there is increased venous pressure in the portal bed. Thus the designation *chronic congestive splenomegaly* has arisen. Cirrhosis of the liver, cavernous transformation of the portal vein, portal vein and splenic vein thrombosis, or variants in the anatomy of the venous pattern have been found in as many as 60 per cent of the cases. Active congestion in the spleen in the absence of venous obstruction has also been proposed as a cause of this syndrome. This concept depends on the hypothesis that disease of the splenic arteries is the primary fault, with the result that they fail to control the amount of blood entering the spleen, thus permitting congestion to develop.

The hematologic changes observed in the Banti syndrome are attributable to the unequal distribution of the cells of the blood in the splenic vascular bed and the remaining parts of the circulation resulting from stasis of the portal circulation. Following splenectomy the blood values usually have returned to normal.

Pathology. The spleen weighs 600 to 1,200 Gm as a rule, but may weigh as much as 5,000 Gm. At first one finds an increase in the reticulum, cellular hyperplastic pulp, degenerative changes in the follicular arterioles, and congestion. Later the follicles become smaller, while fibrosis of the reticulum, trabeculae, and capsule increases. Perifollicular hemorrhages, and siderotic nodules deposited in

the fibrous tissue around the arterioles are found in many instances.

Symptoms. Young adults are most frequently affected, but the disease may come on in childhood. The onset is usually insidious. The condition may ultimately attract attention in a variety of ways. There may be gastrointestinal complaints of vague character, probably attributable to the large mass in the left upper quadrant; the mass itself may be noticed accidentally; symptoms of anemia may become prominent; or the disorder may be announced explosively by the occurrence of a gastric hemorrhage. The spleen may extend to the pelvic brim. Ultimately the symptoms and signs of cirrhosis of the liver may appear. Obstruction of mesenteric veins may lead to the development of hemorrhoids; occlusion of the portal vein is followed by the appearance of signs of collateral circulation.

The anemia is normocytic and moderate in degree unless hemorrhage has occurred, when it may be microcytic hypochromic in type. In cases with long-standing and severe liver disease the anemia may be macrocytic. Leukopenia is found consistently, and thrombocytopenia is observed frequently. The bone marrow may show no abnormality, or slight myeloid hyperplasia may be present.

Diagnosis. Other conditions leading to pancytopenia (p. 1324) must be excluded, as well as the various causes of splenomegaly (p. 233). Even when gastrointestinal hemorrhage has occurred, the diagnosis should be made only after other possibilities have been excluded. Thus, a "silent" peptic ulcer may produce hypochromic microcytic anemia with slight splenic enlargement. Hookworm infection may produce chronic hypochromic anemia with moderate splenomegaly. Liver function should be studied in suspected cases, and esophageal varices looked for. If liver function is good and other conditions have been excluded, portal or splenic vein thrombosis should be suspected. Congestive splenomegaly due to extrahepatic causes is more likely to be found in patients below the age of eighteen than in older patients.

Prognosis and Treatment. Unless serious hemorrhage ensues, the course of the disease is slow as a rule and relatively benign. Patients may live for 10 years or longer. The chief nonsurgical procedures are administration of a diet rich in protein and otherwise complete as well; administration of iron if there has been hemorrhage; and blood transfusion if bleeding has occurred recently. If there is gastroesophageal bleeding, abdominal exploration is advisable, since some cause for congestion in the portal bed may be discovered and treated. At one time splenectomy was the sole surgical measure employed. However, although this procedure is likely to relieve the leukopenia—and thrombocytopenia if it is present—it is of little value in relieving

the portal hypertension. Now, therefore, it is considered that a surgeon should not perform splenectomy in congestive splenomegaly unless he is prepared to form a venovenous anastomosis with the object of reducing the increased pressure in the portal bed. Portacaval shunt is usually preferred because of the large size of the vessels involved. If a large-caliber splenic vein is available or when the portal vein is obliterated, splenectomy and spleno-renal shunts are recommended. When an adequate shunt cannot be made, esophagogastricomy is employed. Following removal of the spleen, the leukopenia disappears, the anemia is relieved in whole or in part, and the platelet count is also likely to be restored to normal. The risks of surgery in these patients are substantial, however, and surgical intervention is advocated only (1) in cases in which there is severe upper intestinal bleeding and in which the portal hypertension is due to extrahepatic block; and (2) in cases of portal hypertension associated with cirrhosis of the liver where ascites and icterus are minimal or absent and there is a reasonable degree of hepatic reserve.

GAUCHER'S DISEASE

Definition. This is a rare, chronic familial disorder characterized by marked splenomegaly and often also by skin pigmentation, pinguiculae of the scleras, and bone lesions.

Etiology, Morbid Anatomy, and Pathogenesis. The disorder usually is apparent early in life. It has a predilection for females, and the condition has been observed most often in Jewish families. Its mode of inheritance is uncertain. The characteristic finding is widespread reticulum cell hyperplasia, these cells being filled with lipid, mainly sphingolipids, as discussed elsewhere (Chap. 95). Consequently, Gaucher's disease is classed as a disturbance of lipid metabolism. The cause is unknown. The cells are distinctive, being 20 to 80 μ in diameter, round, oval, or spindle-shaped, and possessing one or more small, eccentrically placed nuclei. Appropriately stained, the cytoplasm shows numerous wavy fibrillae. These cells are found in the spleen, bone marrow, lymph nodes, and liver. The spleen may weigh as much as several thousand grams.

Symptoms. There is considerable variation in the age of onset and in the rate of progression of symptoms. As a rule, the earlier the onset the more rapid the course. The enlargement of the spleen is usually the outstanding manifestation, sometimes the only one. There may be a dragging sensation or pain due to infarction. Pain in the limbs, due to bone involvement, may develop. The liver may be enlarged, but the lymph nodes usually are not palpable. Roentgenograms may reveal osseous changes. Hemorrhage from the nose or gums is relatively

common. Light yellowish-brown discolorations on the conjunctivas on either side of the cornea, and an ochre-to-brown hue of the skin, may be present.

As in other splenic disorders, moderate anemia, leukopenia, and thrombocytopenia are the usual blood findings.

Diagnosis. Diagnosis can be made by sternal or splenic puncture, which will reveal the characteristic cells. The plasma acid phosphatase activity is increased (p. 780).

Treatment and Prognosis. Although the disease coincidentally involves other parts of the reticuloendothelial system, splenectomy is worthwhile if the spleen is very large and thereby causes discomfort, or if there are serious symptoms attributable to the blood changes. In infants the prognosis is not good, but those who have survived to adolescence may live for many years even if splenectomy is not performed.

NIEMANN-PICK DISEASE

This is a lipid disorder of the reticuloendothelial system very similar to Gaucher's disease except that the condition has been observed only in infancy and its course is much more acute, death occurring within a few months after birth. The characteristic cells are filled with small, round, hyaline droplets, grouped in clusters and giving the appearance of a honeycomb. The stored material is a phospholipid, perhaps sphingomyelin (see Chap. 95).

HAND-SCHÜLLER-CHRISTIAN DISEASE

Exophthalmos, diabetes insipidus, and defects in the membranous bones form the triad which characterizes Hand-Schüller-Christian disease. At one time the manifestations of this disorder were considered to be produced by the growth of a characteristic type of granulation tissue with cells containing cholesterol and its esters. The present tendency is to regard Schüller-Christian disease as being closely related to Letterer-Siwe disease and to eosinophilic granuloma. *Eosinophilic granuloma* is a disorder localized to bone, consisting of solitary or multiple osteolytic lesions, but with no discernible visceral involvement. It is found in infants, children, and young adults, and occasionally at a later age, and is treated satisfactorily by curettement or roentgen therapy. *Letterer-Siwe disease* has been observed most often in infants and young children, is variable in duration (a few weeks to several years), and has often proved fatal. There is evidence of a wasting disorder, with enlargement of the spleen and liver, generalized lymphadenopathy, a hemorrhagic diathesis, especially petechiae and purpura, skeletal lesions, progressive anemia, and cutaneous manifestation of dis-

crete, yellowish-brown maculopapular lesions, or papules with a red border and yellow center. They are scattered over the face and trunk particularly, but may be found in the scalp and elsewhere. Whitish macules over the palate and tongue and weeping erosions in the axillae and other moist areas may develop. The three conditions possess as a common denominator a distinctive, inflammatory histiocytosis. Some regard Letterer-Siwe disease as the acute or subacute form of a disorder of which the Schüller-Christian picture is the chronic counterpart. The onset of the latter is in children and in young adults. The histiocytosis or granulomatosis may or may not be accompanied by intense eosinophilic reaction; the characteristic lipogranuloma is now thought to be the late phase in the evolution of the histiocytic lesion. Unlike Gaucher's disease and Niemann-Pick disease, there is no family predilection, and splenomegaly and hepatomegaly do not always occur and are never conspicuous. The blood may show pancytopenia. Death may not ensue for many years, but considerable disability may occur in the interval.

differential diagnosis was considered. In this section the clinical manifestations of Hodgkin's disease and of other conditions chiefly affecting lymph nodes, such as lymphosarcoma, will be described. These disorders will be considered under one heading because their clinical manifestations are very similar.

Definition. Hodgkin's disease, lymphosarcoma, giant follicular lymphoblastoma (lymphoma), and reticulum cell sarcoma are included in this group. They are characterized by painless, progressive enlargement of lymphoid tissue. Lymphadenopathy is a characteristic feature, and the spleen is frequently enlarged. Cachexia, anemia, and, in many instances, fever usually are late symptoms.

History. A disorder affecting the "absorbent glands and spleen" was described by Hodgkin in 1832. *Lymphoblastoma*, *malignant lymphogranuloma*, and many other terms were used in referring to the disease in subsequent descriptions. Jackson and Parker attempted to classify the disorder in three categories—paragranuloma, granuloma, and Hodgkin's sarcoma. The picture of lymphosarcoma was described by Kundrat in 1893; Brill, Baehr, and Rosenthal differentiated giant follicular lymphoblastoma in 1925. Roulet (1932) separated reticulum cell sarcoma from the general group of malignant diseases of lymphoid tissue. Some pathologists differentiate still other groups or call these by other names; others seek to avoid fine separations.

Classification. Clinically these disorders vary considerably in severity. Histologically they show marked differences, but these are not well correlated with the clinical picture. They have been classified in various ways on histologic grounds. One of the most simple is that which differentiates those conditions with a simple histologic pattern from those with more complex patterns. In the first category are reticulum cell sarcoma and lymphosarcoma. The proliferating cells tend to encroach upon, obscure, and finally replace the architecture of the lymph node. The histologic pattern of Hodgkin's disease is more complex. Lymphocytes, plasma cells, granulocytes (eosinophilic and neutrophilic), monocytes, fibroblasts, and giant cells make up the picture. The giant Reed-Sternberg cells, 10 to 40 μ in diameter, are possessed of abundant cytoplasm, a multilobed nucleus or multiple nuclei, and prominent nucleoli. A variable amount of fibrosis may be present, and the lymph node architecture is often lost. In giant follicular lymphoma the histologic pattern is also somewhat complex, but the striking feature is the presence of multiple, follicle-like nodules of various sizes. Other types of "lymphoma," difficult to classify, are observed from time to time.

Etiology. Hodgkin's disease forms about one-third to one-half of all cases of this group. It affects a younger age group than the other conditions, be-

243 HODGKIN'S DISEASE AND OTHER "LYMPHOMAS"

M. M. Wintrobe

In an earlier chapter (p. 231) the causes of lymph node enlargement were discussed and their

ing most common in the second and third decades. However, no age is immune. Males are more frequently affected than females.

The cause of these disorders is unknown. There may not even be the common denominator of neoplastic growth to unite them, for many investigators consider Hodgkin's disease to be an infectious granuloma. Efforts to transmit the disease to animals have failed, however, and attempts to incriminate various organisms, including the tubercle bacillus (human and avian), diphtheroid bacilli, and *Brucella* organisms, have not succeeded. An agent in the lymph nodes found to produce encephalitis on inoculation into animals appears to be a non-specific chemical substance derived most probably from eosinophilic leukocytes. The other disorders in this group are assumed generally to be true neoplasms. This applies even to giant follicular lymphoma, which at first was considered a benign disease.

Symptoms. In most cases lymph node enlargement, usually cervical, is the first symptom to attract attention. This may be bilateral but is more often unilateral at first. More rarely the axillary or the inguinal nodes are the first to enlarge. The nodes are discrete and movable at first; only later do they become matted together and fixed. As a rule, they are painless and not tender, and the overlying skin is normal. However, when they have developed rapidly or when nerves are infiltrated as well, they may be painful. This is true in Hodgkin's disease especially. The size of the nodes ranges from that of a pea to that of a large orange. There is a resilient firmness in most instances, but the growth of connective tissue may make the nodes of Hodgkin's disease harder in the course of time. Occasionally the nodes in the axillary or inguinal regions may become secondarily inflamed and even break down.

After an interval varying from months to years, evidence appears of lymph node involvement elsewhere. This may affect other superficial nodes: supraclavicular, axillary, inguinal, subpectoral, brachial, or femoral. A common site, also, is the mediastinum, to which such symptoms as cough, dyspnea, stridor, or dysphagia should attract attention. Splenomegaly develops in more than half the cases of Hodgkin's disease and of giant follicular lymphoma; less frequently in the other forms. The liver is often palpable. Ultimately cachexia develops and weight loss occurs.

The mode of onset of these disorders may vary greatly, however. The manifestations may arise first in the mediastinum, the lungs, the digestive tract, the genitourinary tract, the bones, and, rarely, the nervous system. Infiltration of the lungs, atelectasis, or pleural effusion may occur. In the gastrointestinal tract the tumor may be far advanced before

it is first discovered. Colicky pain, loss of weight, anemia, a palpable tumor, and obstruction are signs produced by lymphosarcoma of the small intestine. When the retroperitoneal nodes are the chief ones to enlarge, the diagnosis may be very difficult to make and the chief symptoms may be fever, pain, and loss of weight. Hematuria, pyuria, or pain is found when the genitourinary tract is involved. Localized pain and tenderness, spontaneous fractures, and neurologic changes due to extension into the spinal canal from vertebral lesions are the most common manifestations of bone involvement. Areas of rarefaction may be demonstrable in roentgenograms, although symptoms may be present long before roentgenographic signs become evident. Subperiosteal infiltration may occur, or the bone marrow involvement may be extensive. Of cutaneous manifestations, pruritus is the most frequent; it is encountered particularly in Hodgkin's disease. Brownish skin pigmentation, herpes zoster, and nodules produced by infiltration by the specific cells are among other skin manifestations which may be encountered. Symptoms and signs may also develop which are secondary to swellings producing pressure in various areas.

Constitutional symptoms may appear early in Hodgkin's disease, but they occur late in the other lymph node disorders. Hodgkin's disease, in particular, may produce a great variety of manifestations, so that, in addition to the localized form, which is much the most common, a generalized type, an acute type with death in a few weeks or months, a "larval" or abdominal form, and a splenomegaly type have been described.

Fever is common in Hodgkin's disease, although the well-known Pel-Ebstein type of fever is actually uncommon, appearing no oftener than in 16 per cent of cases. This form of fever consists of febrile periods of several days' to several weeks' duration in which the temperature remains at levels of approximately 102 to 104°F, alternating with periods of weeks to even months during which there is no fever whatever.

Blood Picture. The greatest degree of variation is found in the blood picture associated with these disorders. There may be no changes whatever. On the other hand, there may be profound anemia as well as striking changes in the leukocytes and platelets. In Hodgkin's disease, changes in the blood occur relatively early. The anemia in Hodgkin's disease is usually only moderate in degree and normocytic in type; very occasionally, hemolytic anemia develops. The total leukocyte count in Hodgkin's disease may be slightly or moderately increased, it may be normal, or there may be leukopenia. Sometimes the leukocyte count may exceed 25,000 per cu mm. The differential count may show neutrophilia, relative and absol

cytopenia, monocytosis, or eosinophilia. All these changes may be present at the same time, or none of them. Eosinophilia, which is mentioned frequently as characteristic of Hodgkin's disease and which may sometimes be very pronounced, is found only in about 20 per cent of cases. An absolute increase in the number of lymphocytes suggests some disease other than Hodgkin's. Neutropenia suggests extensive bone marrow or splenic involvement.

The leukocyte picture in the other forms of disease chiefly affecting lymph nodes is more frequently normal than in Hodgkin's disease. Relative and even absolute lymphocytosis may be seen. The lymphocytes may be of normal types, but unusual forms and "tumor cells" (p. 1330) have been described. Monocytes may be increased in number and young forms may be seen, but a consistent and characteristic picture has not been described.

The platelet count may be increased in Hodgkin's disease, and large, bizarre forms may be seen. It is more common, however, to find the platelet count normal. In some instances thrombocytopenia is present; this usually occurs when leukopenia is found as well. The presence of thrombocytopenia suggests extensive bone marrow or splenic involvement and is usually, although not necessarily, a grave sign.

Bone Marrow Picture. As would be expected from this description of the blood findings, changes in the bone marrow are not characteristic and are seldom helpful except in rare cases of so-called "bone marrow Hodgkin's," in which there is extensive involvement of the bone marrow. Reed-Sternberg cells have been demonstrated in the bone marrow in a few cases of Hodgkin's disease. Lymphocytosis may be found in the bone marrow in some cases of lymphosarcoma and of giant follicular lymphoma. Such cases raise serious doubt as to whether there is any true difference between them and chronic lymphocytic leukemia.

Diagnosis. The differential diagnosis of lymph node enlargement was discussed in an earlier chapter (p. 231). Cases in which there is little or no enlargement of the superficial lymph nodes present the most difficult problem in diagnosis, for then a variety of inflammatory and neoplastic disorders of the mediastinum, lungs, gastrointestinal tract, or liver must be considered, and the possible presence of chronic infections such as brucellosis must be ruled out. Hodgkin's disease, in particular, may produce such varied manifestations that this disorder must be kept in mind almost whenever diagnosis is obscure. This disease is particularly suggested by such symptoms as relapsing fever, loss of weight, and splenic or hepatic enlargement, together with anemia and leukocytosis or leukopenia.

Treatment. Surgical excision, irradiation, and

chemotherapy all have their place in the treatment of these disorders. Surgery is useful when the condition is definitely localized, irradiation is effective in the treatment of local manifestations and when the disease is generalized, and chemotherapy is particularly indicated when the disorder is widespread. Sometimes all three forms of therapy can be employed, and frequently there are advantages in using both irradiation and chemotherapy.

Since these conditions, in many instances, appear to arise locally and only disseminate later, *surgical excision* should be an excellent form of therapy. Unfortunately, correct diagnosis is not often made early. Furthermore, in many instances in which the disease seems to be local, dissemination has already occurred or has been present from the beginning. Nevertheless, this form of therapy, when appropriately applied, offers the only chance of cure. Surgical excision, if undertaken, must be radical and should be followed by irradiation or chemotherapy or both. Surgery, in the form of splenectomy, should also be considered when signs of "hypersplenism" are present: severe anemia with shortened life span of transfused red corpuscles, leukopenia, and thrombocytopenia.

Röntgen rays represent the preferred method of *irradiation*, apparently being somewhat superior to the use of radioactive phosphorus and more effective than radium. Generally speaking, segmental or localized irradiation is used rather than total irradiation, except when generalization has taken place. Various areas are treated in succession. The decision as to dosage is the problem of the radiotherapist. The total amount depends on the response of the lesions to therapy, the general effects on the patient, and the effect on the blood. The effect of irradiation may be dramatic, large masses melting away in the course of a week. Pressure symptoms may disappear; fever and pruritus, if present, may be relieved; and pain caused by bone involvement may be alleviated. Pulmonary lesions may decrease in size and pleural effusions may clear. Anemia may disappear and the leukocyte count, if elevated, may drop to normal. In other cases, irradiation is less effective, in some instances being of scarcely any benefit. Prediction in advance as to the likelihood of benefit from therapy is often difficult. In general, the more chronic and slowly growing forms respond best to therapy. Remission following treatment may last but a few weeks or may persist a year or longer. In some cases such improvement can be reproduced many times by additional therapy.

The action of *nitrogen mustard* in these disorders is similar to that of irradiation, but in certain cases of Hodgkin's disease this drug seems to be more effective than irradiation. It has been found that

in some cases previously given roentgen therapy and no longer responding to such treatment, nitrogen mustard therapy has been distinctly beneficial. Other cases treated with nitrogen mustard from the beginning have responded well and, in general, in a manner similar to that already described under roentgen therapy. Fever often disappears promptly, and anemia, if present, also is alleviated. Abnormalities in the leukocytes may revert toward normal although the immediate effect, noticeable within 5 to 14 days following the first dose of nitrogen mustard, may be leukopenia and an increase of anemia. Thrombocytopenia, if present at the initiation of therapy, is less likely to be relieved by treatment.

Nitrogen mustard [methyl-bis(β -chloroethyl)-amine hydrochloride, HN2] is given intravenously in doses ranging from 0.1 to 0.3 mg per kg body weight per injection each day. As much as 0.8 mg per kg has been given in a course of therapy, but the usual amount is 0.4 to 0.6 mg. The drug is available in vials containing 10 mg. To prevent thrombosis, an intravenous infusion of normal saline solution is first introduced, and when this is flowing freely, 10 ml saline solution is added to the vial containing the mustard. The drug dissolves readily. The appropriate dose is then withdrawn and injected through the rubber tubing of the saline infusion. Nausea and even vomiting may follow several hours after injection of the drug, but are usually of shorter duration, even though sometimes more intense, than in irradiation sickness. The nausea and vomiting can be allayed or prevented by giving chlorpromazine in three 20- to 30-mg doses, 6 and 4 hr before and at the time of the injection.

The discovery of other chemotherapeutic agents has reduced the comparative importance of nitrogen mustard in the treatment of the various forms of leukemia and the lymphomas, with the exception of Hodgkin's disease. Triethylenemelamine (p. 1333) appeared at first to be very promising because it has the advantages, as compared with nitrogen mustard, that it can be given by mouth and produces little or no nausea and vomiting. In Hodgkin's disease 10 to 15 mg may be given in a course, and maintenance doses of 5 to 10 mg per month have been employed. Lymphosarcoma, like chronic lymphocytic leukemia, is more sensitive, and 2 to 5 mg may produce an effect. Other lymph node disorders may require amounts intermediate between these quantities. However, the potential hematopoietic depressant action limits its usefulness.

Chlorambucil, an aromatic mustard which can be taken by mouth, has proved to be useful in the treatment of these disorders because its absorption

is more consistent than that of TEM and the effect on the bone marrow is more easily controlled. Since its action is slow, beneficial effects not appearing before 3 weeks as a rule, chlorambucil is especially useful when remission following nitrogen mustard therapy is short-lived and maintenance therapy is required or when intravenous therapy is not practicable. The usual dose is 0.1 mg per kg body weight per day, but in Hodgkin's disease, larger doses may be tolerated. As with other agents of potential hematopoietic toxicity, measurements of hemoglobin, leukocytes, and platelets should be made at regular intervals to avoid serious hematopoietic depression.

Urethan, busulfan, and the folic acid antagonists offer little or nothing in the treatment of the lymph node disorders under discussion, and the steroid hormones are only occasionally and transiently useful. The effects of irradiation and various chemotherapeutic agents are compared in Table 241-1 (p. 1333).

In addition to these measures, general supportive and symptomatic therapy will be required in individual cases.

Prognosis. The most important factor which seems to determine the course of these disorders is their inherent character. Cases of Hodgkin's disease and of lymphosarcoma are known to have run a chronic course for many years. In other instances the course is rapid and progression occurs in spite of therapy. In general, cases with the most favorable outlook are those in which only one accessible lymph node group is affected and where evidences of systemic involvement such as fever, loss of weight, increased sedimentation rate, and changes in the blood are lacking. In the last analysis, a therapeutic trial should be attempted, for a prolonged remission may sometimes be encountered even in cases in which the general examination suggests a hopeless prognosis.

244 MULTIPLE MYELOMA, CRYOGLOBULINEMIA, AND MACROGLOBULINEMIA

M. M. Wintrobe

MULTIPLE MYELOMA

Definition. Multiple myeloma is characterized by the development of multiple tumors of bone which produce pain, pathologic fractures, and anemia. There may be diffuse involvement of the bone marrow, and in the urine or blood a peculiar protein is usually found. Rarely, a localized tumor is the only manifestation. Tumors composed of other types of cells have been described, but the evidence is all in favor of a single type ("myeloma" or plasma cell).

Etiology. The disease appears most commonly after the age of forty and is twice as frequent in males as in females. The cause is unknown. The true nature of the peculiar protein is not clear. It is presumed that the myeloma cell is responsible for the protein anomalies of multiple myeloma. This cell has the cytochemical characteristics of an intensely protein-producing cell, as judged by ultraviolet microscopy. Protein with ultracentrifugal and electrophoretic properties similar to those of the abnormal components present in the plasma in this disease has been extracted from myeloma tumor tissue. Myeloma proteins of various electrophoretic mobilities appear to be related to one another but are not identical; they differ from those of normal serum. Thus the myeloma globulins were found to lack antigenic determinants that are present in the γ -globulins of normal serum. Lakewise investigation of amino acid composition, of N-terminal groups, and of the peptides derived by tryptic hydrolysis has provided evidence that the tumor produces a new type of globulin that differs structurally from normal γ -globulin. The urinary Bence-Jones proteins are not derived by renal cleavage of the myeloma globulins but, in fact, may be their precursors. The paraneoplasia (see below) has been attributed to the production of proteins of such low molecular weight that they are capable of diffusing through the capillary beds of many, if not all, tissues. When these proteins find complementary polysaccharides which they can bind, insoluble complexes are formed and the proteins remain.

Symptoms. Pain is the most frequent complaint and is produced by the tumors which, according to their location, may or may not be discoverable on physical examination. The tumors range from the size of a pea to that of a hazelnut. They are confined, for the most part, to the sites of the red marrow: the ribs, sternum, spine, clavicles, skull, or the extremities about the shoulder or pelvic girdle. Roentgenograms reveal discrete, punched-

out lesions and pathologic fractures. However, in 13 per cent of cases, or more, no significant osseous lesions are found, or only diffuse osteoporosis may be seen. Paraplegia due to compression of the spinal cord is the most common symptom referable to the nervous system, but intercostal neuralgia, radiculitis, diplopia, anisocoria and failing vision, or neuropathy from direct infiltration of nerve roots and peripheral nerves may occur. Anemia, abnormal bleeding, or symptoms suggesting nephritis sometimes dominate the clinical picture. Recurrent bouts of bacterial pneumonia are common. Extravascular involvement of lymph nodes, spleen, tonsils, liver, and other tissues has been described.

Laboratory Findings. Anemia is moderate in degree, as a rule, and normocytic, but sometimes it is severe and macrocytic. Enumeration of the cells may be difficult because of clumping, a peculiarity often related to the great quantity of globulin in the plasma. In blood smears there may be a marked tendency to rouleaux formation. Polychromatophilia, stippling, and even normoblasts may be found in the blood smear. The leukocyte count may be normal, slightly increased, or low. Myeloma cells like those seen in the bone marrow may be found. The platelet count is usually normal.

Hyperproteinemia may be present (50 to 85 per cent of cases), and sometimes extremely high values are found. The increase is due to the globulin fraction. Sometimes the protein precipitates or coagulates spontaneously when the plasma is exposed to low temperatures (cryoglobulin, see below). Its presence may be associated with a variety of symptoms, especially those suggesting the Raynaud syndrome. Detailed studies have revealed that the predominant type of protein differs from one case to another. In the majority of cases, γ -globulin is increased; in others it is β -globulin, and in the minority the substance is an α -globulin. The diagnostic patterns in multiple myeloma as measured by the Tiselius electrophoretic technique are characterized by tall, narrow, sharply defined peaks owing to the presence of large amounts of a relatively homogeneous abnormal protein (Fig. 244-1 B and D).

When the urine is heated, a white cloudy precipitate appears at temperatures of 50 to 60°C, but when the temperature is raised to near the boiling point the precipitate redissolves. Such Bence-Jones protein has been observed in 40 to 50 per cent of cases. As judged by various physicochemical determinations, Bence-Jones proteins are related neither to normal serum proteins nor to the abnormal serum proteins. As judged by serologic reactions, however, they appear to be related to normal serum proteins. Bence-Jones protein can be synthesized readily from free amino acids rather than from tissue protein precursors. There is evi-

FIG. 244-1. Descending patterns (after 250 min) of pooled normal serum (A), and serum from two patients with multiple myeloma (B and D) and one patient with macroglobulinemia (C), determined by electrophoretic analysis at 1°C in 0.1 ionic strength. Veronal buffer at pH 8.4 to 8.5. Note the large γ -globulin component (γ_1) in (B) and the β -globulins in (D), as well as the γ -globulin (γ_1) in the case of macroglobulinemia (C). The very narrow β_2 peaks in (A) and (B) are anomalies, probably due to lipoproteins, and are not unusual in serums from nonfasting subjects. (Courtesy, Drs. Emil L. Smith and B. V. Jager and Mr. Douglas M. Brown.)

dence that myeloma serum globulins may be conjugated glycoproteins containing a significant quantity of carbohydrate bound to the protein component. In contrast, the urine myeloma proteins seem to be devoid of any significant carbohydrate component.

In addition to the hyperproteinemia and the Bence-Jones proteinuria, a third form of protein abnormality may be observed in multiple myeloma. This is the deposition of a peculiar protein in the tissues, producing atypical amyloidosis or *paramyloidosis*. This has been observed upon histologic examination in 6 to 10 per cent of cases of multiple myeloma.

Not infrequently, certain chemical changes are found in the blood. *Hypercalcemia* has been observed in 20 to 53 per cent of cases, values of 12 to 16 mg per 100 ml being not unusual. With progression of the disease the hypercalcemia may increase. The high serum calcium levels have been attributed to the resorption of bone which takes place, but they are further increased by secondary hyperplasia of the parathyroids caused by renal impairment. As a rule, the hypercalcemia is not accompanied by a decrease in the inorganic serum phosphorus or by much increase in alkaline phosphatase, thus differing from the changes found in primary hyperparathyroidism.

The serum uric acid concentration is not infrequently increased, and nitrogen retention has been noted in many cases. Both these changes can be ascribed to the renal damage associated with the deposits of Bence-Jones protein which are found not only in the distal tubules but in the entire nephron up to the proximal convoluted tubules. The resulting distention and obstruction to renal flow lead to glomerular atrophy and ultimate renal failure ("myeloma kidney"). It is thus not unusual in multiple myeloma to find albumin, casts, and renal epithelial cells in the urine, and evidence of renal functional impairment as well as nitrogen retention often develop.

The *bone marrow* frequently contains the tumor cells, although their number may range from 3 to 96 per cent. The myeloma cell is moderately large (15 to 30 μ), and round or ovoid, and contains a round, eccentrically placed nucleus which may contain one or two nucleoli. The chromatin is moderately coarse. The cytoplasm is bright blue. Attempts have been made to classify myeloma cells according to their maturity and to establish some correlation to the clinical manifestations of the disease. Some tendency for patients with the more mature cell types to live longer and for those with greater percentages of immature cells to manifest

renal involvement has been observed, but extreme variations have been encountered in individual cases, and no consistent correlation between cell type and extent of bone involvement, hyperglobulinemia, Bence-Jones proteinuria, or the electrophoretic distribution of the various globulin fractions has been established.

Diagnosis. The multiple bone lesions, the excretion of Bence-Jones protein, the hyperproteinemia, and the characteristic cells in the bone marrow form a combination of findings which makes the diagnosis evident. Difficulty arises when back pain, obscure anemia, or some complaint of nonspecific character has failed to suggest this disease and the appropriate examinations have not been made; or when extrasosseous tumors exist. Sometimes the picture may closely simulate hyperparathyroidism (see p. 604). Paper electrophoresis of serum and urine now provides a means for the ready detection of the protein abnormalities characteristic of multiple myeloma. When both serum and urine have been examined, a significant abnormality has been detected in 97 per cent of cases. The distinctive feature is the tall, narrow, sharply defined peak due to the presence of large amounts of a relatively homogeneous abnormal protein.

Prognosis and Treatment. The prognosis is unfavorable. The average duration is 2 to 3 years. Great variations occur, however, and some patients live for many years. Local irradiation is often helpful and may be strikingly so if there is a single bone lesion. The effects of irradiation on myeloma are rather unpredictable, however. Urethan is perhaps the best therapeutic agent currently available but even its value is limited. Although subjective improvement is associated with its administration in about half the cases, objective improvement has been observed in only about 20 per cent. To achieve any benefit, doses of 2 to 5 Gm daily have to be given for periods of 6 to 10 weeks. With these doses nausea and vomiting may develop and may necessitate withholding the drug. Other chemotherapeutic agents, including stilbamidine, nitrogen mustard, and triethylene melamine, are of even less value. The steroid hormones may sometimes be helpful but often have been disappointing.

CRYOGLOBULINEMIA AND MACROGLOBULINEMIA

History, Definitions, and Clinical Syndromes. Although multiple myeloma and Bence-Jones proteinuria were recognized in 1845, the presence of a cold-precipitable protein in the serum of a patient with this disease (*cryoglobulin*) was not described until almost a century later (Wintrobe and Buell, 1933). *Macroglobulins*, high molecular weight proteins demonstrable only by ultracentrifugation, and

a syndrome associated with macroglobulinemia were described in 1944 (Waldenström). Since that time, with the exploitation of electrophoretic, ultracentrifuge, and serologic techniques, considerable attention has been attracted to the occurrence of aberrations in protein metabolism in association with various diseases and, sometimes, in the absence of any associated disorder. In some instances it appears that the unusual findings represent only increases of normally occurring protein molecules (*dysproteinemias*, Chap. 89), whereas other studies suggest that they denote aberrant protein synthesis (*paraproteinemia*).

Cryoglobulinemia of minor degree (less than 25 mg per 100 ml) may be encountered in a large variety of disorders, including systemic lupus erythematosus, rheumatoid arthritis, periarteritis nodosa, chronic lymphocytic leukemia, lymphosarcoma, polycythemia rubra vera, kala-azar, subacute bacterial endocarditis, coronary artery disease, hepatic cirrhosis, and numerous other diseases. Rarely, the cold-precipitable protein is present in large amounts and is associated with atypical Raynaud phenomena, purpura, bleeding from nose and mouth, retinal hemorrhages, cold sensitivity, cyanosis, mottling, and even gangrene of the lower extremities. Multiple arterial and venous occlusions may occur. Rouleaux formation, pseudoagglutination of the red cells, and an elevated erythrocyte sedimentation rate are likely to be found as well. In most instances of this sort, multiple myeloma has been demonstrated and, rarely, other disorders, such as chronic lymphocytic leukemia. In a few instances no underlying disease entity could be demonstrated (*essential cryoglobulinemia*).

The concentration of cryoglobulin in plasma or serum has ranged from trace amounts to 10 Gm per 100 ml. The amount may vary over the course of the illness in the same patient. The minimum concentration of cryoproteins required for massive reversible precipitation is about 1 Gm per 100 ml. The precipitation of the plasma protein is due to its decreased solubility in the blood and can be demonstrated *in vitro*. The most commonly occurring cryoglobulins have been found in the gamma fraction, but globulins in the alpha fraction, in the beta fraction, and between the beta and gamma peaks have also shown this property. Molecular weights have ranged from 165,000 to 600,000.

Macroglobulinemia is detectable with certainty only by ultracentrifugal analysis. The molecular weight of the macroglobulins is greater than 1 million. Trace amounts of macroglobulins are present in normal serums. The term *macroglobulinemia* is applied to serums containing more than 5 to 10 per cent of components sedimenting with a Svedberg constant greater than 15. Pathologic macroglobulin molecules have the electrophoretic mobility of β -

or γ -globulins or are intermediate between these two. Occasionally an abnormal plasma protein may be both a cryoglobulin and a macroglobulin.

Macroglobulinemia has been observed in neoplastic diseases, collagen disorders, chronic infections, amyloidosis, and cirrhosis. Serums of multiple myeloma have seldom been reported to show abnormal high molecular weight components. In the syndrome described by Waldenström, *primary macroglobulinemia*, in contrast to multiple myeloma, focal bone lesions are not found, there being at most a diffuse osteoporosis, but slight to moderate lymphadenopathy and hepatosplenomegaly are characteristically encountered. Bone pain is conspicuously absent. In clinical features, *primary macroglobulinemia* thus resembles *lymphosarcoma* rather than multiple myeloma. Symptoms and signs of vague ill health, some weight loss, lassitude, dyspnea, and recurrent infections are common, as well as pallor and edema. Sjögren's syndrome (dryness of mucous membranes in eye, nose, mouth, and vagina) has been described in association with *macroglobulinemia*. Epistaxis and mucosal bleeding are frequent. Anemia, usually normocytic, is present; leukopenia, relative lymphocytosis, sometimes eosinophilia or monocytosis, as well as thrombocytopenia, hemolytic anemia, and pancytopenia have been observed. Bence-Jones proteinuria and *paramyeloidosis* such as are seen in multiple myeloma have been reported. The bone marrow characteristically shows large numbers (40 to 80 per cent) of small, atypical "lymphocytic" cells with protoplasmic shedding and "naked nuclei." The erythrocyte sedimentation rate is markedly elevated. Bleeding time, coagulation time, and prothrombin time may be prolonged, and prothrombin consumption may be impaired. On paper electrophoresis, a symmetric gradient with a narrow, sharp, and high peak in the globulin fraction is found, most often in the γ position. In the latter instances the Sia or water test (see below) is positive.

Pathology and Pathogenesis. In the secondary forms of dysproteinemia and paraproteinemia the pathologic findings are those of the underlying disorder. In the "primary" disorders no specific changes have been noted except for the signs of reticuloendothelial hyperplasia and the bone marrow and lymph node infiltration with small atypical lymphocytes which have been observed in *primary macroglobulinemia*. When *cryoglobulinemia* has been present, pulmonary arteriolar obstruction has been described, as well as vascular occlusion elsewhere (kidneys, etc.). Symptoms associated with *cryoglobulinemia* have been attributed to precipitation of cryoprotein in peripheral blood vessels as well as to cold agglutination of red cells by this protein *in vivo*. The bleeding tendency has been attributed to intravascular precipitations with secondary capil-

lary damage and, in some cases, to defects in platelet function.

No uniformity in the physicochemical characteristics of macroglobulins has been demonstrated. Macroglobulin peaks in the electrophoretic diagram are sharp and cannot be differentiated from myeloma proteins (Fig. 244-1,C). Macroglobulins frequently sediment in the ultracentrifuge as multiple components. Studies of their amino acid composition have shown variations from patient to patient. It is uncertain from immunologic studies whether the macroglobulins and cryoglobulins represent increases of normally occurring protein molecules or denote aberrant protein synthesis.

Plasma cells are thought to be the source of cryoglobulins and atypical lymphocytic cells the source of macroglobulins, but more primitive or more malignant precursors of these cell types are also thought to produce these unusual plasma proteins.

Diagnosis. Hyperproteinemia is found in most cases and is generally attributable to a great increase of globulin, usually γ -globulin. In most instances the globulin fraction amounts to 4 to 8 Gm per cent. The Sia test, which involves mixture of the patient's blood with distilled water and observation of the formation of a precipitate when positive, has not been found to be a reliable screening test for *macroglobulinemia*. The electrophoretic pattern of severe *macroglobulinemia* is indistinguishable from that of multiple myeloma. Immunologic diagnosis with antimacroglobulin serum has been successful in most cases studied, but ultracentrifugation should be carried out in suspected cases since it yields the critical evidence.

The diagnosis of *cryoglobulinemia* offers no particular difficulty, but since cryoglobulins have a wide thermal amplitude, blood for these studies should be drawn into warm syringes and separation of serum or plasma carried out at 37°C. Cold precipitation reversible on warming is characteristic. The differential diagnosis of *cryoglobulinemia* should include consideration of cryofibrinogens and cold agglutinins.

Macroglobulinemia should be distinguished from *purpura hyperglobulinemica*, characterized by dependent purpura and hypergammaglobulinemia. The characteristic electrophoretic γ -globulin peak in this syndrome is a broad hump, in contrast to the sharp peak of *macroglobulinemia*.

Prognosis and Treatment. The prognosis in the secondary forms depends upon the nature of the underlying disease process. The primary disorders are compatible with survival for several years. If death occurs it is usually due to severe anemia, complicating infections, or the hemorrhagic diathesis. ACTH or adrenocorticosteroid therapy has sometimes seemed to be helpful.

Section 2: The Cardiovascular System

A. DISEASES OF THE VASCULAR SYSTEM

245 HYPERTENSIVE VASCULAR DISEASE

John P. Merrill

Arterial hypertension in man may be arbitrarily divided into two categories: pulmonary hypertension and systemic hypertension (Table 245-1). The more important problems related to pulmonary hypertension are considered in Chap. 262.

Systemic hypertension is the manifestation of an abnormal state of the circulation, just as fever is a sign of altered temperature regulation. The word *hypertension* in itself implies nothing as to the associated prognosis or organic vascular or renal disease. Indeed, the role of elevated blood pressure in the production of aggravation of vascular disease is a disputed but important association which will be discussed separately. As a clinical phenomenon, hypertension may be diagnosed if on repeated examinations the blood pressure is found to be above that considered normal for adolescents of similar racial and environmental background. In North American adults, 140/90 may be regarded as abnormally high arterial pressure; for coolies in Peiping, 125/80 might have a similar significance.

It is now apparent that the hypertensive syndrome has no single clear-cut etiology. Many factors are involved, some of which may be thought of as mere exaggerations of the physiologic mechanisms by which normal arterial pressure is maintained. Others are obviously abnormal in the sense that they play little or no role in normal circulatory regulation and are prominent only in disease states. Any or all of these factors may be involved in any given case of hypertension. It is not surprising, therefore, that in spite of a vast amount of interest

and work no single therapeutic agent for the treatment of hypertension has come to light. The physician or student who undertakes to study or treat hypertension must seek to understand the various mechanisms which may be involved when he attempts to evaluate their importance in the individual problem.

FACTORS DETERMINING BLOOD PRESSURE

Blood flow through the normal vascular bed may be thought of as a system in which pulsatile flow occurs in a series of elastic tubes. The larger tubes, represented by the arteries, gradually decrease in caliber through the arterioles to the capillaries and similarly decrease the magnitude of each pulsation until in the capillaries the flow becomes steady. In this system the pulsating force is provided by the contraction of the left ventricle, the elasticity by the walls of the arteries, and the major portion of the resistance to flow by the arteriolar bed. The pressure produced at the peak of ventricular contraction in this elastic system is represented by the systolic blood pressure, and the total resting resistance of the system in ventricular diastole by the diastolic pressure. The difference between these two values is the pulse pressure. The mean arterial pressure is usually thought of as one-half the sum of the systolic and diastolic pressures. However, the true mean pressure, which is the average pressure throughout the cardiac cycle, is not faithfully reflected by this value, since the fall in pressure from the systolic to the diastolic level is not a decline over a steady slope. In measuring the arterial blood pressure, the observer is assessing a

 5. Miscellaneous
 - a. Coarctation of the aorta
 - b. Increased intravascular volume

* Any of the conditions associated with diastolic hypertension may become rapidly progressive (malignant).

value which is determined by a number of factors not ordinarily measured directly.

We may consider these factors in order:

1. Since increasing resistance to flow is developed by increasing viscosity, *blood viscosity* is one factor altering blood pressure. Blood viscosity is influenced chiefly by the concentration of the plasma proteins and of the white and red corpuscles suspended in it. Marked polycythemia may thus give rise to hypertension both by reason of increased blood viscosity and by the increased whole blood volume.

2. The amount of whole blood or plasma in the intravascular compartment contributes also to the arterial pressure. Since the intravascular fluid except for the blood proteins is continuous across the capillary walls with extracellular fluid in general, the volume of this latter compartment also contributes to arterial blood pressure. Thus severe de-

pletion of either or both compartments by bleeding or acute dehydration will produce hypotension; increase of the volume of either may result in hypertension. An increase in intravascular volume alone, however, may give rise to an increase in neither blood pressure nor cardiac output if the ability of the autonomic nervous system to prevent such change is not exceeded. Failure of the cardiac output to respond to increased intravascular volume may also prevent increase in blood pressure. Possibly for this reason patients with cyanosis and congenital heart disease who have increased blood volumes fail to show hypertension as do many patients with other forms of heart failure who have an increase in blood volume but no increase in blood pressure. Thus modification of one of the factors by another or all of the others may influence the alteration in blood pressure.

3. In a sense, the rebound of the elastic arterial walls in ventricular diastole serves to maintain the propelling force of the blood in the interval between systolic contractions. It thus serves, together with the peripheral resistance to flow in the arteriolar bed, to maintain the resting or diastolic pressure in the vascular system. The effect of decreasing elasticity of the large vessel walls may be seen particularly in the elderly arteriosclerotic patient. Here, failure of the rigid vessel wall to distend with the systolic thrust of the heart results in a sudden increase in pressure in the system, producing a high systolic pressure. Similarly, lack of elastic "recoil" results in a rapid drop of pressure in diastole, and this failure to maintain the resting pressure in the vascular bed may be recorded as a low diastolic pressure.

4. An increase in cardiac output, such as is mediated through exercise, fever, or thyrotoxicosis, may cause increases in blood pressure by increasing the amount of blood pumped into the vascular system per unit of time. Since the effect is primarily a result of the ventricular contraction, the predominant effect upon blood pressure is an increase of the systolic phase. As a clinical phenomenon, this has much less significance for the hypertensive syndrome than does elevation of the diastolic blood pressure. Decrease in cardiac output secondary to severe myocardial damage results in hypotension. If compensatory vasoconstriction occurs, the diastolic pressure may be relatively well maintained, and the hypotension is characterized by a low systolic and a narrow pulse pressure.

5. The single most important factor in the production of the type of arterial hypertension with which the physician is usually concerned is an increase in peripheral resistance. The greatest part of this increase is contributed by the arteriolar segments. Relatively small changes in caliber cause marked changes in resistance, which varies inversely

as the fourth power of the radius of the lumen. Thus a decrease of 10 per cent in the average arteriolar lumen will lead to a rise of 30 per cent in mean arteriolar resistance. The diastolic pressure, which represents the residual resistance in the peripheral vascular bed after systole, more closely reflects the factor of peripheral resistance. As reflecting this factor, elevation of the diastolic pressure is of crucial importance in the syndrome concerned in a study of hypertension in man, though systolic hypertension alone, which may result from several causes of increased stroke volume, may have little bearing in itself. *Decrease* in arteriolar tone secondary to toxins, nervous influence, or drugs results in increase in caliber and may produce *hypotension*.

Alterations in blood pressure, in either direction, produced by changes in any of the five factors previously mentioned are modified by reflex arcs of the autonomic nervous system. Through vasoconstrictor or vasodilator fibers, these arcs change arteriolar tone and lumen following appropriate stimulation of receptors on the afferent side of the arc. Similar reflex arcs modify the cardiac output. Medullary centers exist for control of cardiac rate as well as for vasoconstrictor and vasodilator effects. These medullary centers in turn may be influenced by higher vasomotor centers situated in the hypothalamus and possibly even in the cerebral cortex. Stimulation of vagal afferent fibers located in the aortic arch and the heart may result in alteration in caliber of the blood vessels through impulses transmitted via these vasomotor centers over efferent fibers to the vasculature. A rise in blood pressure, by stretching special proprioceptors in the aortic wall, is thought to be the stimulus for the resultant depressor response. Similar receptors are located in the carotid sinus. Stimulation of these by increase in pressure may lead to vasodilator responses, whereas decrease in pressure may produce a vasoconstrictor reflex through the afferent limb of the reflex arc. The sinus and aortic nerves are the so-called "buffer nerves" and together make up an important mechanism for controlling arterial blood pressure. The rise in diastolic pressure which occurs when the upright position is assumed is one of the many important manifestations of this control.

INCREASES IN BLOOD PRESSURE SECONDARY TO CHANGES IN ARTERIOLAR CALIBER

From the foregoing, it would appear that factors which influence arteriolar tone and caliber play an important role both in maintaining normal blood pressure and in producing hypertension. The following factors have been thought to be of importance in influencing arteriolar tone.

Decrease in Vasodilator Tone. Some authorities hold that the kidney elaborates a vasodilator substance whose production is impaired in renal disease or nephrectomy. Practical applications of this theory are lacking in the clinical hypertensive syndrome.

Humoral Agents Which Raise Smooth Muscle Tone. For more than half a century, workers in the field of hypertension have been interested in circulating humoral substances whose primary action is to increase arterial tone. Some of these substances have been thought to arise in the central nervous system, but the greatest interest has centered around the release by a kidney, whose blood supply has been compromised (though not made anoxic), of a substance (renin) which, by interaction with a serum globulin, is capable of causing an increase in smooth muscle tone in arterioles. The resultant pressor substance (angiotensin) has been investigated, and in some cases antisera to renin, which will prevent its action in animals, have been prepared. Serotonin, which causes a variable pressor response, is among many other substances found in the plasma of hypertensive animals. Investigators have isolated from dogs a pressor substance, released from the central nervous system on centripetal vagal stimulation, which has common properties with serotonin and has been postulated as an explanation for the failure of so-called "neurogenic" hypertension to respond to sympathectomy. To the great misfortune of the hypertensive population, the role of all these substances in chronic hypertension in man is still obscure. The hormones of the adrenal medulla, however, are humoral agents which can and do play a well-defined role in some instances of human hypertension. Primarily implicated are epinephrine and its demethylated analogue, norepinephrine. From the physiologic viewpoint, norepinephrine appears more closely associated with the human hypertensive syndrome. Its action is characterized by an increase in peripheral resistance (primarily because of increased small vessel tone) with no increase, or an actual fall, in cardiac output. Functioning tumors of the adrenal medulla and chromaffin tissue elsewhere can closely mimic the clinical picture of hypertensive disease, although in "essential" hypertension blood levels of norepinephrine are not elevated.

Humoral Agents Which Potentiate either Neurotonic or Humoral Tonic Effects. It has been suggested that the kidney may be the site of a vasoexciter material (VEM) which potentiates (in the experimental animal) the response of small arterioles to topical application of epinephrine. Of much greater significance, however, is recent evidence both in the experimental animal and in human beings that the kidney's role in renal hypertension may be its failure to excrete or to metabolize a cir-

culating pressor substance similar to, or identical with, norepinephrine. It has been known for some time that the synthetic analogue of the sodium retaining hormone of the adrenal cortex (DOCA) may potentiate the rise in blood pressure caused by pressor agents. Recent studies on the naturally occurring hormone, aldosterone, have great pertinence for the understanding and therapy of hypertension. Patients with adrenal cortical adenomas secreting excess aldosterone may have hypertension. With bilateral adrenal hyperplasia and excess aldosterone production, *malignant hypertension* is frequent. In these instances not only is the blood pressure markedly elevated but there is coexistent vasculitis. The effect appears not to be due simply to sodium retention since such patients show high urinary sodium excretions and have no increase in blood volume. Patients with malignant hypertension from any cause may show a striking increase in aldosterone excretion. Since such patients invariably have renal vascular involvement, and since the injection of purified angiotensin causes a rise in aldosterone, excretion of the latter may be a secondary result of renal origin.

Nervous Constrictor Influence. As an explanation for the increased peripheral resistance which appears to be common to the hypertensive syndrome almost independent of its etiology, it is natural to inquire into the role of increased vasomotor tone. Increased vasomotor tone and augmented spontaneous vasomotor activity have been observed experimentally under the microscope, and are well known to occur in many hypertensive and prehypertensive patients. Many factors which block or reduce sympathetic tone at cortical levels, such as psychotherapy and sedation, and sympathectomy and sympatholytic drugs at a more peripheral mechanism, tend to decrease blood pressure. Similarly, factors known to augment constrictor nervous influence, such as emotion and chilling, tend to increase blood pressure. The hypertensive individual tends to have an increased pressor response to the infusion of norepinephrine, to cold stimuli (cold pressor test), and to the augmented blood pressure that follows termination of the Valsalva maneuver (Valsalva overshoot). Possibly in some cases the central nervous system participates by elaboration of the humoral agent. It should be remembered, also, that the adrenal medulla is under the influence of nervous stimulation. When the autonomic pathways are interrupted by chemical blockade of the sympathetic ganglions, it has been found that in both normo- and hypertensive patients blood pressure falls are greater when the initial blood pressure is high. In both normo- and hypertensive patients, however, elevation of the blood pressure by the administration of norepinephrine leads to a decrease in the extent of the blood pressure fall which may

be obtained by ganglionic blockade. In spite of the fact that vasomotor activity is not always increased in essential hypertension, it is reasonable to conclude that neurogenic mechanisms play prominent contributory roles. In established hypertension, the vasomotor centers continue to regulate blood pressure levels in response to both pressor and depressor stimuli. In hypertensive individuals, however, the "set" of the regulatory mechanism is at higher levels of blood pressure. Thus, although "fixed" hypertension is rare, nervous influences, however, play a lesser role in well-established or malignant hypertension because of the increased participation of humoral factors, or because of decreased reactivity of the blood vessels secondary to pathologic change.

CONSTITUTIONAL FACTORS IN HYPERTENSION

In attempting to assay the significance of alterations in blood pressure in the light of the various factors which have been delineated, it is most important to remember that range of blood pressure compatible with normal activity and good prognosis may be extremely wide when compared with the range of such parameters as body temperature. This is truer, perhaps, of the systolic than of the diastolic variation, but it is to be emphasized that daily or even hourly fluctuations in blood pressure per se may be without real prognostic significance.

In infancy, arterial pressure may be 70/45. It then rises in late infancy and early childhood to values approximating 80/55, and by adolescence reaches levels of 95 to 110 systolic and 65 to 80 diastolic. The upper limit arbitrarily chosen by many for the "normal" blood pressure in the adult is 140/90. All values cited above are approximations, and fluctuations in either direction may occur without true prognostic significance. Lower values are often diagnosed and treated as "low" blood pressure because of the well-perpetuated myth that "normal" systolic blood pressure should equal the sum of 100 plus chronologic age. Levels based on this formula, however, should be regarded as a statistically common misfortune rather than the ideal concomitant of advancing years. In the absence of obvious causes for true hypotension, values below that proposed by such a formula are, in fact, likely to be correlated with longevity. In more than a third of the population, however, arterial hypertension, as manifested by resting blood pressures of 150/90 or above, may be noted as a transient phenomenon in early adult life, and as the usual finding beyond the age of sixty. Although in themselves such increases in blood pressure may be of little significance in any one individual, statistics based on hundreds of thousands can leave no doubt that

even occasional rises in resting levels of pulse and blood pressure are associated with a shortening of the life span.

Factors of importance in alterations of arterial blood pressure may also be found in a consideration of race, environment, individual heritage, and state of activity. Thus, hypertension occurs earlier and in a higher percentage of Negroes, both in the United States and in tropical Panama, than in white or Indian populations. Evidence from such surveys suggests that the increased incidence of hypertension may be correlated with an increased incidence of subclinical pyelonephritis. Women develop hypertension slightly more frequently than men but appear to tolerate it better. The basal pressures determined on awakening, before morning activity begins, are lower than during the day: 90/60 in many healthy whites, and 80/50 or less in many natives of the tropics and of Asia. Sitting or standing normally raises the diastolic levels 5 to 10 mm Hg; exercise and hypoxia, or marked anemia, lower the diastolic and raise the systolic level.

Recent statistical studies indicate that, although blood pressure tends to rise with age in the relatives of both hypertensive and nonhypertensive individuals, blood pressure elevations are found earlier in the relatives of the hypertensive population, and tend to remain higher throughout their life span. Similarly, hypertension frequently develops earlier and with greater severity in successive generations with hypertensive predecessors. Whether this predisposition represents an accentuated tendency for blood pressure elevation in hypertensive individuals and their relatives or whether one may interpret such data as an overlapping of two population groups, hypertensive and nonhypertensive, is not at present clear. In those with the hypertensive predisposition, inherited or not, a rise in systolic and diastolic pressures may be caused by chilling, anger, frustration, anxiety, or even pleasant anticipation of an exciting event; whereas others with no predisposition may show no rise, even with the most intense emotional stimuli. The value obtained with the sphygmomanometer is thus only one of the many factors whose importance must be assessed in considering the significance of alterations in blood pressure.

CLASSIFICATION OF HYPERTENSION

A system of classification of hypertension is presented in Table 245-2. It should be noted that systemic hypertension may be differentiated by reason of the phase in which the elevation occurs. Marked elevation of systolic pressure with little or no elevation of diastolic pressure has a different etiologic connotation and, even more important, an entirely

Table 245-2. CURABLE HYPERTENSION

<i>Systolic hypertension only</i>	<i>Combined systolic and diastolic hypertension</i>
Thyrototoxicosis	Brain tumor
Arteriovenous fistula	Unilateral renal disease
Anemia	Adrenal cortical hyperfunction
	Aldosteronism
	Cushing's syndrome
	Pheochromocytoma
	Pituitary tumors
	Coarctation of the aorta
	Increased intravascular volume
	Clampusia
	Polycythemia

different prognostic significance than does elevation of the diastolic phase. As has been pointed out previously, predominance of systolic elevation depends more upon the factor of cardiac output. Predominance of diastolic elevation is a manifestation of increased residual resistance in the peripheral vascular bed after systole and, as such, more closely represents the clinically significant abnormality in the hypertensive syndrome. The term *essential hypertension* has been employed to indicate those cases of hypertension for which a specific endocrine or renal basis cannot be found, and in which the neural element may be only a mediator of other influences. Since even this latter relationship is not entirely clear, it is more properly listed for the moment in the category of unknown etiology. The term *essential hypertension* defines simply by failing to define; hence it is of limited use except as an expression of our inability to understand adequately the forces at work. Nevertheless, the bulk of patients with significant and persistent elevation of diastolic pressure form a fairly uniform group for which no well-defined etiologic process has been delineated. From the standpoint of wide acceptance, the term probably should be retained. Unquestionably, cases of essential hypertension in the progressive form may develop a renal component which perpetuates this syndrome as a result of development of vascular lesions in the kidney. The development of vascular lesions here and elsewhere has served for some authors to differentiate *hypertensive disease from hypertension*, which latter term connotes only elevation of blood pressure without associated vascular lesions. The prognostic significance of this division is obvious, but the dividing line is often difficult to draw. *Essential hypertension* may be further subdivided into two types, *benign and malignant*. These terms should be employed only as relating to the rapidity and severity of the vascular disease accompanying increased blood pressure levels. The malignant type may be superimposed upon the benign type; occasionally,

however, it may be so rapid in onset and so severe in its course as to appear a separate entity. In addition, the severity and rapid progress of vascular disease associated with hypertension primarily renal in origin may justify the term *malignant hypertension*.

Many factors involved in the hypertensive syndrome have now been delineated. It may be permissible to attempt to integrate them in a theoretic case of human "essential" hypertension in a fashion which lays much stress upon the primary role of nervous vasoconstrictor influences. In this idealized view an individual, by reason of inherited traits, including race and sex, may be particularly susceptible to vasomotor reactions resulting from a stressful environment. Specific reasons for this susceptibility might include emotional instability, a labile vasomotor apparatus, possibly including the vasomotor center in the medulla, and a peripheral vasculature which hyperreacts to nervous constrictor stimuli. Such an individual would manifest early in life greater rises in blood pressure in response to environmental stimuli than his fellow born without these genetic traits. Such abnormal responses might be elicited by the cold pressor test and Valsalva maneuver. During early adult life these rises would be more frequent, reach higher levels, and tend less and less to return to so-called "normal" values. The continued stress of pressure upon a genetically sensitive vasculature might then result in small blood vessel changes which would be manifest in the optic fundi and kidneys. With the involvement of the kidneys and possibly the adrenals, a second, humoral mechanism might originate which could then overlay and finally completely dominate the original neurogenic origin. At this point, although the labile vasomotor response might still be elicited, its importance from an etiologic and therapeutic standpoint would be secondary. Such a formulation is admittedly speculative. It does, however, fit many of the observed facts. Although many doubt that increased pressure per se may cause vascular disease, in the author's view, the statistical correlation in mortality tables is too impressive to neglect. By analogy, too, the pulmonary vascular disease that may result from prolonged increased pulmonary arterial pressure with mitral stenosis suggests very strongly that this relationship may obtain.

A second and possibly more important classification has been constructed in Table 245-2. Such a table emphasizes the fact that the physician confronted with the problem of hypertension must think first of those situations in which the hypertension may be associated with a specific defect which may be amenable to specific therapy. A causal relationship of this type may be difficult to establish and may be defined only by the resultant success or failure of therapy. Nevertheless, the op-

portunity to "cure" hypertension must be sought diligently in each hypertensive patient.

The diagnosis and treatment of *thyrotoxicosis* have been discussed in Chap. 66. The presence of an *arteriovenous fistula* may be manifested by systolic hypertension and a wide pulse pressure, and may be diagnosed by the presence of a murmur or thrill over the site of the abnormal communication. This may be over the peripheral vessels where involved, or a typical "machinery murmur" may be heard over the left precordium in the case of patent ductus arteriosus. Both of these conditions may be amenable to surgical correction.

Adrenal cortical hyperfunction may be manifest by hypertension as well as the other signs of Cushing's syndrome (Chap. 68). Osteoporosis, hirsutism, "buffalo hump," striae, and disorders of glucose metabolism are typical. Hypersecretion of aldosterone and its relation to hypertension are discussed elsewhere in this chapter and in Chap. 68. Patients with hypertension with hypopotassemic alkalosis should be evaluated carefully for this syndrome. Two factors may confuse the diagnosis. The common administration to hypertensive patients of thiazide diuretics may cause potassium depletion. The administration of diets low in sodium may prevent hypopotassemia in hypertensive patients and alkalosis in patients with full-blown hyperaldosteronism.

Pheochromocytoma, though rare, produces a completely curable form of hypertension when surgery is performed before the vascular disease has become irreversible. In spite of such diagnostic techniques as perirenal air injection and retroperitoneal insufflations with oxygen, the newer pharmacologic agents for provocative and blocking tests, the assay of urinary pressor amines and their metabolites (VMA), the diagnosis remains extremely difficult and may be established only by exploration. Pheochromocytoma, in addition to the typical intermittent attacks, may produce a steady hypertension. The problem is discussed further in Chap. 69.

The diagnosis of *coarctation of the aorta*, if considered, will usually be made by comparison of blood pressure in the arm and leg, and appropriate x-rays of the chest may show the typical notching of the ribs.

The problem of unilateral renal disease as a cause of hypertension has received increasing attention with the advent of newer diagnostic methods and forms of surgical therapy. Occlusion of a renal artery or one of its branches should be suspected when malignant hypertension appears suddenly in patients with no previous history. A strong family background of hypertension in a patient with longstanding disease may make the coexistence of a renal lesion and hypertension coincident rather than causal. A marked discrepancy in renal size as indi-

cated by intravenous pyelography is an important clue. If enough functioning parenchyma remains, increased concentration of contrast medium may be evident on the side with the vascular lesion. Obstruction of renal arterial flow may cause hypertension even when intravenous pyelography reveals no difference between the two kidneys. The measurement of the uptake and excretion of radioactive iodopyracet (Diodrast) or iodohippurate sodium (Hippuran) may be made by counters placed over the renal area, following the intravenous injection of the isotope. This has proved an innocuous and frequently helpful screening test. Simultaneous comparison of the function of the two kidneys by samples obtained from each ureter may yield important information, particularly when there is no discrepancy in over-all function as measured by the intravenous pyelogram. Characteristically, the kidney whose arterial inflow is impaired shows a smaller volume of urine with a higher osmolality and creatinine concentration and a lower sodium concentration than on the contralateral side. Translumbar aortography or renal arteriograms made by the injection of contrast media directly into the renal arteries by a catheter passed percutaneously up the femoral artery may directly visualize the affected vessel. None of these tests, however, is infallible, and the data from all of them should be compared before surgical intervention is decided upon. If, at exploration, obstruction of one renal artery is found, with a marked pressure drop across the area of obstruction, and if the contralateral kidney is normal, removal of the affected kidney or the placing of an arterial graft may be curative. Involvement of the contralateral side by vascular disease, however, may militate against surgical cure, even when the obstruction is relieved. With correction of the obstruction, however, hypertension due to mild vascular change on the contralateral side may respond to medical therapy. It is the duty of the internist to keep in mind that mild to moderate hypertensive disease may respond to medical therapy, even when conclusively due to unilateral renal disease. This fact must be weighed carefully against the morbidity and mortality of renal vascular surgery.

Polycythemia, as a cause of increased intravascular volume, may be diagnosed upon estimation of the hematocrit and erythrocyte count. Phlebotomy, the administration of phenylhydrazine hydrochloride, radioactive phosphorus, and irradiation have been used successfully in treatment.

Pituitary tumors, accompanied by hypertension, may be associated with the picture of hyperadrenalism or with that of acromegaly, in which case the characteristic facies, increase in head, hand, and foot size, as well as x-rays of the extremities and

sella turcica, may confirm the diagnosis. The therapy of choice is irradiation.

TOXEMIAS OF PREGNANCY

The toxemias of pregnancy are arbitrarily divided into preeclampsia and eclampsia. Eclampsia is characterized by a more severe course and more diffuse lesions; it differs from preeclampsia by the presence of convulsions and coma. The syndrome is manifested by hypertension, proteinuria, and retention of fluid. Common symptoms are headache, visual disturbances, and epigastric pain. In the past the incidence of eclampsia has varied from 0.2 to 1.5 per cent. With better prenatal care, however, this incidence has markedly decreased in recent years. The disease is more common in primiparas than in multiparas, though this may reflect only the decreased tendency of toxemic primiparas to become pregnant again. Diabetes, multiple births, and hydatidiform moles are all reported as increasing the incidence of toxemias. The primary pathologic lesions are seen in the kidneys, and consist of thickening of the walls of the glomerular capillaries and the capillary basement membrane. In the more severe cases, petechial hemorrhages and small areas of necrosis are found in the brain. In severe eclampsia, the liver shows characteristic lesions consisting of irregular areas of hemorrhage and necrosis. This may occasionally be severe enough to produce jaundice. Bilateral symmetric necrosis of the cortices of the kidney occurs most often at the onset of eclampsia. The etiology is still obscure. Many of the reported cases of eclampsia may be simply the aggravation, by the pregnant state, of preexisting essential hypertension or of glomerular nephritis. When these can be shown to be absent in the first 5 months of pregnancy, it is postulated that a toxic or pressor substance formed in the placenta, possibly at the site of placental infarction, may be implicated in the production of the profuse vascular lesions.

Course. True eclampsia or preeclampsia rarely manifests itself before the sixth month of pregnancy. In the cases which are carefully followed, the earliest clues may be headache, anorexia, proteinuria, elevations of blood pressure, and excessive gain in weight. There is frequently some degree of oliguria in eclampsia, and in severe cases, frank renal failure with anuria may supervene. Marked hematuria is not usually seen except in association with cortical necrosis. In the absence of frank renal failure, renal blood flow is usually normal, but there is characteristically a depressed filtration rate. In the severe cases, convulsions are characteristic and may be the cause of death. Termination of pregnancy is usually accompanied by marked improve-

ment, although symptoms may continue for as long as 24 to 36 hr after delivery. The recovery stage is usually characterized by a drop in blood pressure and a profuse diuresis with loss of edema. The prognosis is good in carefully managed patients without severe renal lesions. The internist must concern himself with the possibility of the development of permanent renal disease or hypertension following eclampsia. Unfortunately, there is no agreement on the frequency with which this occurs. In most of the reported series, some renal disease and hypertension persist following eclampsia, but it is not clear whether this is due to aggravation of preexisting renal disease and hypertension, or whether it dates specifically from the eclampsia. Severe previous eclampsia in women over thirty-five contraindicates a further pregnancy. In the presence of slight hypertension or minimal urinary findings, the patient may be allowed to become pregnant and should be carefully followed during her pregnancy, with the possibility of electively terminating it when signs of eclampsia appear. There is no good evidence that normal, well-conducted pregnancy aggravates mild "essential" hypertension if toxemia does not supervene. Patients with preexisting renal disease, however, may do poorly, particularly if functional impairment exists.

The treatment of toxemia should be divided into prophylactic and therapeutic measures. Prophylaxis consists of careful surveillance with restriction of sodium to less than 2 Gm per day if edema appears. The treatment of severe eclampsia is the termination of pregnancy. Medical measures are similar to those outlined for the treatment of hypertensive encephalopathy. Magnesium sulfate, as well as protoveratrine and reserpine, have been used with good results. It has been reported that the use of hydralazine (Apresoline) in the hypertensive disease of toxemia of pregnancy is more specific than for other forms of hypertension. Massive doses of penicillin, which appear to exert some antitoxic action, have been used with some success, and good results have been reported from the prophylactic use of stilbestrol.

SYSTEMIC HYPERTENSION

Signs and Symptoms. The signs and symptoms of hypertension can rarely be attributed to the elevated blood pressure itself. A large number of patients with elevated blood pressure may have no symptoms or signs whatever. In the more advanced stages of hypertensive disease, signs and symptoms depend upon the organ involved by the vascular disease accompanying the hypertensive process. These include, of course, cerebral arterial and arteriolar disease, coronary artery disease, congestive

heart failure, and renal failure, which will be discussed in separate chapters. A not infrequent early symptom is the presence of headache. This may take any form but classically is a dull, pounding occipital headache, which is present upon awakening in the morning and tends to wear off during the day. Many patients with hypertension complain of nonspecific difficulties such as weakness, nervousness, flatulence, palpitation, and dizziness. Since hypertensive patients are prone to emotional and psychic difficulties, it is frequently difficult to evaluate these symptoms.

Epistaxis may occur, as well as microscopic and even gross intermittent hematuria accompanied by moderate proteinuria. The latter findings may signify vascular involvement of the kidney, but should alert the physician to the possibility of preexisting renal disease. An important physical finding, which may give some clue to prognosis and progress of the vascular disease, is the change in the vessels of the optic fundi. The damage caused by hypertensive disease is better recognized by a careful study of the retina than by any other means. These changes deserve careful attention and should be accurately described in the patient's record. The physician should note exactly what he sees in the retina and not use one of the grades or classifications currently employed. The grading method is useful for statistical studies by one person or group, but a subsequent examiner cannot be sure that he and the previous examiner understood exactly the same changes implied by a numerical grade. If possible, the lesions when seen should be described as to character and location and, even better, drawn. Early changes in the retinal vessels include diminution in the caliber of the smaller vessels most distal from the disk. A convenient standard of reference is to relate the arteriolar diameter to that of the vein. Generalized constriction or "spasm" of the arterioles may be seen in severe toxemia of pregnancy. A more specific lesion, however, is segmental constriction of the arterioles. This is a permanent lesion and characteristic of significant diastolic hypertension. Tortuosity of the larger vessels close to the disk appears in hypertensive disease, but may also be seen in arteriosclerosis without hypertension, and is of little significance to the hypertensive process itself. Arteriovenous nicking is characteristic of chronic moderate hypertension but may also be seen in those patients with severe elevation of diastolic blood pressure. True arteriovenous nicking requires the presence of an open space between artery and vein on both sides of the artery (Fig. 245-1). Frequently, a darker red area in that portion of the vein just peripheral to the crossing may be seen, representing stasis of venous flow at that point. Since both segmental constriction and arterio-

FIG. 245-1. Retinal changes of hypertension—arterio-venous compression and segmental constriction of the arterioles (S. A. Shelburne, *Ann. Internal Med.*, 1957.)

venous nicking are permanent changes, they represent evidence of a preexisting hypertensive state. As such, they may have important diagnostic importance in a patient who at the time of examination has a drop in blood pressure secondary to myocardial infarction or hemorrhage.

An increased light reflex signifies thickening of the vessel wall. With advancing changes, small flame-shaped hemorrhages and glistening white exudates may make their appearance. A serious prognostic sign, indicative of advanced disease, is papilledema, manifested by blurring of the disk margins. This should be particularly evaluated at the temporal margin, since some degree of blurring of the nasal margin may be physiologic. Separation of the retina has been observed in the acute hypertensive episodes of eclampsia. Although somewhat unusual, there may be marked differences in the degree of involvement of the retinas. The visual symptoms usually depend upon the degree of involvement and the location of the lesions.

Patients with hypertensive disease occasionally suffer from acute episodes characterized by marked rise in blood pressure above the previous level, and by disorders of the nervous system which last for minutes, hours, or days, and then disappear without clinical evidence of lasting damage. Such episodes, described as *hypertensive encephalopathy*, are not limited to any single etiologic type of hypertensive disease but are particularly common in association with renal disease, especially where a common factor, such as acute glomerulonephritis or disseminated lupus erythematosus, has produced both vas-

cular lesions and hypertension. Spasm of cerebral vessels is generally thought to be the cause of these attacks, although adequate demonstration of this has yet to be made. Small thrombi and edema play a role in some cases. This syndrome may frequently simulate the hypertensive crises of pheochromocytoma or mimic brain tumor. The clinical syndrome appears in two forms, depending upon whether the disturbances in the nervous system are chiefly of generalized or of focal nature.

The general form usually appears in individuals without previous long-standing hypertension. It may occur in women with eclampsia and in children and young adults with acute glomerulonephritis. Rapidly progressing malignant hypertension is frequently accompanied by hypertensive encephalopathy. Aside from a rapidly rising blood pressure, the attacks are characterized by headache, visual disturbances which may progress to blindness, papilledema, vomiting, stupor, coma, stertorous breathing, psychoses, and convulsions. All these manifestations may be hastened and enhanced by the administration of excessive amounts of fluid.

The focal type of hypertensive encephalopathy may appear in any individual with chronic hypertension, but is especially frequent in older individuals and in the malignant form of the disease. Loss of consciousness, convulsions, and paralysis involving one-half of the body are especially common, and the clinical picture, though reversible, may exactly resemble cerebral vascular accident due to hemorrhage, thrombosis, or embolism, at the beginning. The differentiation may be impossible until the patient has been observed for a number of hours or even for several days.

Prognosis in Hypertension. Few problems in clinical medicine are as difficult or as controversial as the evaluation of the prognosis for any individual patient with early but marked hypertension. Although the statistics of the insurance companies clearly indicate that, in general, the mortality experience is increasingly unfavorable with progressive elevation of the blood pressure, individual variation in tolerance to hypertension and hypertensive disease is marked. A few of the factors affecting prognosis have already been mentioned. In Table 245-3 are listed factors which are known to affect adversely the prognosis in patients with hypertension. These are listed in order of increasing gravity. Systems of classification of hypertension, characterizing the disease in varying grades of severity and with varying prognoses, have been devised on the basis of (1) retinal changes and (2) a combination of the factors listed in Table 245-3, plus phenolsulfonphthalein excretion and response to sodation. It can be concluded that young male patients of racial origins known to be susceptible to hypertensive disease, with high, relatively fixed

Table 245-3. FACTORS INDICATING AN ADVERSE PROGNOSIS IN HYPERTENSION

Negro origin
 Youth and male sex
 Persistent diastolic pressure > 110
 Marked cardiac enlargement
 ECG changes of ischemia or left ventricular strain
 Renal functional impairment
 Retinal hemorrhages and exudates
 Angina pectoris
 Myocardial infarction
 Cerebrovascular accident
 Congestive heart failure
 Marked retinal arteriolar sclerosis
 Nitrogen retention*
 Papilledema

* Nitrogen retention, when due to vascular disease of the kidney, indicates a very grave prognosis. Its occurrence in primary renal disease with only mild hypertension may be less important.

diastolic pressures, are apt to do badly. On the other hand, women apparently tolerate elevated blood pressure and even hypertensive vascular diseases better than do men. Every physician interested in hypertensive disease has followed women and an occasional man through many years of relatively good health with persistent diastolic pressures of 120 mm or more. The degree of retinopathy may give some clue as to the prognosis, although this, in general, is a better guide to the progress than to the ultimate prognosis, since even severe retinopathy may be reversed occasionally by appropriate therapy, and rarely improves spontaneously. Papilledema and renal insufficiency are extremely grave prognostic signs in every instance. The occurrence in the hypertensive patient of myocardial infarction, congestive heart failure, or cerebral vascular accident signifies a poor prognosis, although, again, every hypertensive clinic has its share of patients constituting exceptions to this general rule. Emotional instability, while making the treatment somewhat more difficult, does not otherwise affect prognosis itself. Poor response to adequate treatment of any sort, including failure to correct obesity, frequently indicates impaired prognosis.

Diagnosis. The diagnosis of hypertension may be made with a blood pressure cuff, and the diagnosis of hypertensive vascular disease by the usual methods for evaluating the cardiovascular system, kidneys, and optic fundi. The differential diagnosis should, from the very first, include disease states giving rise to hypertension for which more specific therapy exists. A list of these, which should be considered during the first evaluation of any hypertensive problem, is given in Table 245-2.

Treatment

Principles of Therapy. Whatever the form of therapy selected, it must not be forgotten that the physician who treats hypertension is treating the patient as a whole rather than the separate manifestations of a disease. The first principle of the therapy of hypertension is the knowledge of when to treat and when not to treat. Two essentially opposing viewpoints are maintained in this regard, with various shades of opinion in between. Both agree that the accelerated phase of hypertension with a high diastolic pressure, and rapid progress of vascular lesions in the retinas, heart, and kidneys, markedly affects the prognosis and justifies any form of treatment aimed at lowering the blood pressure, except in the presence of marked nitrogen retention. The differences are sketched in Table 245-4.

The viewpoint indicated on the right in Table 245-4 is espoused by the author, and henceforth the discussion of therapy will be oriented from this point of view.

Selection of Patients for Therapy. In the decision to institute treatment, the factors delineated in the paragraph on prognosis must bear considerable weight. Factors of increasing gravity, shown in Table 245-3, are increasingly important indications for specific therapy. Frank nitrogen retention, however, may contraindicate and obviate any specific form of depressor therapy. Sudden, marked, and persistent elevation of diastolic pressure may precede signs and symptoms and, as such, indicates need for therapy. A knowledge of when to withhold specific treatment is equally important. A woman who has tolerated her diastolic pressure of 120 for 10 years without symptoms or deterioration does not need immediate specific treatment for hypertension. Marked elevation of systolic pressure, with little or no rise in diastolic, does not constitute an indication for depressor therapy. This is particularly true in the elderly or arteriosclerotic patient, even though the diastolic pressure may also be moderately elevated. A trial of mild forms of therapy, including psychotherapy, reducing diets, sedation, or mild depressor agents, which fails to improve signs or symptoms, may justify more intensive forms of therapy. The physician must, however, carefully weigh the value of making his patient "blood pressure conscious" by a specific regimen and regular follow-up, against real need for any particular form of therapy. Above all, in treatment or prognostication, he must avoid engendering in the patient a fear of the disease which may be unwarranted in our present state of knowledge. Promising therapies are available, however, and it should be remembered that the forms of treatment are not mutually exclusive. Particularly, it should be remembered that the confidence, patience, and

Table 245-4. OPPOSITE VIEWPOINTS ON THERAPY OF HYPERTENSION

The exact level of the blood pressure may have little clinical significance, since it correlates poorly with the incidence of vascular disease and with mortality figures. Treatment of hypertension per se is unjustified.

Spontaneous remissions of hypertensive vascular disease, tolerance of it, and response to nonspecific therapy make results of specific hypotensive therapy difficult to evaluate. In a few cases vascular disease has progressed in hypertensive individuals in spite of the fact that adequate lowering of the blood pressure has been obtained with hypotensive agents.

The dangers and side effects of "specific" therapy may be worse than the natural course of the disease.

enthusiasm of the physician are important ingredients in any form of therapy. The hypertensive process being what it is, this factor undoubtedly accounts in large part for the varying degrees of success achieved by different investigators with the same therapeutic program.

Symptomatic Therapy. Improvement in symptoms, as well as blood pressure levels, frequently results from adequate psychotherapy (see below). For the relief of hypertensive headache, elevation of the head of the bed during the night is usually beneficial. Thiocyanate salts have been used with some success, although the necessity for carefully checking blood levels of this drug to prevent toxicity has greatly decreased its usefulness. Not infrequently a cup of black coffee or the administration of 200 to 400 mg caffeine as the citrate or sodium benzoate salt, given on arising, may help the hypertensive headache. Periodic venesection has met with occasional success in alleviating headache and dizzy spells. Small amounts of sedation in properly selected patients may be of some value. They should be carefully evaluated after preliminary therapeutic trial for the undesirable side effects. With renal failure, the short-acting barbiturates Seconal and Amytal are preferable to phenobarbital, since they do not require the renal route for their excretion. Because sedation may play a more fundamental role in hypertension than that of symptomatic therapy, its use becomes a highly individualized problem. The administration of 30 mg phenobarbital three to four times a day to one patient may well dull the knife-edge of anxiety and result in improvement. In other individuals, the mental confusion that may result, as well as the necessity for taking medica-

The level of diastolic pressure may not correlate with vascular disease or mortality in the individual, but in a large series it can be statistically shown to shorten the life span.

In spite of the variables, irreversible fatal vascular disease may result from essential hypertension. There is reason to believe that elevation of the diastolic pressure contributes to this, and in the absence of knowledge of other factors and with the ability to lower blood pressure with specific therapy, attempts to lower pressure seem justified in properly selected cases.

Various effective forms of hypotensive therapy exist, including psychotherapy. It is justifiable to apply mild therapy to mild forms of hypertension, and since the problems and dangers of therapeutic methods increase with increasing order of efficacy, they may be justified in severe forms of the disease. In experienced hands specific forms of therapy, even though dangerous, need not be delayed until irreversible changes have taken place.

tion continually, may do more harm than good. The conscientious executive, faced with a problem which he is capable of solving with a clear head, does not benefit his hypertensive disease by grappling with his problem under the influence of sedatives which cloud his thinking. Such situations must be carefully assessed on their individual merits. The tranquilizing agents (Miltown, Equanil) may be useful in allaying anxiety and tension without impairing critical faculties.

Psychotherapy. A majority of patients with essential hypertension have disorders of personality which may be aggravated by environmental or emotional stress resulting in conflicts and anxiety which may be correlated with fluctuations in blood pressure. Although there is little agreement on the specific personality patterns involved, such emotional contributions may be recognized frequently, they are particularly evidenced in the tense, anxious individual with marked fluctuations in blood pressure. In such cases, psychotherapy alone has produced results equal to the best of other forms of therapy. It is, moreover, an indispensable adjunct to them. Intensive psychotherapy may not be necessary and, indeed, should not be undertaken unless it can be followed to completion, since the early part of the exhaustive psychiatric approach may often be followed by exacerbation of hypertension. One should not underestimate the value of the psychotherapy resulting from a good physician-patient relationship. It is probable that just this resulted in the improvement in hypertension attributed to nostrums such as watermelon seed and garlic. It follows from this example, however, that an emotionally labile patient, with numerous emotional

problems and psychosomatic complaints, cannot always be told—because of the absence of vascular or renal disease—simply to forget his problems. In the vast majority of instances, a discussion of the problem with reassurances fortified by mild medication and follow-up visits at infrequent but regular intervals will do more good.

Dietary Management. Obesity is frequently a sign as well as a complication of the hypertensive personality. Since it has an undoubted adverse effect upon prognosis and progress of the disease, it should be specifically treated by an adequate weight-reducing regimen, such as has been outlined in Chap. 22. The patient should fully understand the necessity for this regimen without being frightened by it.

There can be no question but that, in the hands of certain workers, diets low in sodium and in protein have resulted in striking amelioration of hypertensive vascular disease. Of these, the so-called "rice diet," containing 200 mg sodium, 25 Gm protein, and approximately 2000 nonprotein calories, is an example. Recent work has indicated that it is the low sodium content rather than the protein deficiency that is responsible for the beneficial results. The true rice diet probably does not maintain nitrogen balance, and it must be strictly adhered to for at least 6 to 8 weeks, during which time most patients find it extremely unpalatable. More palatable diets may be planned which contain less than 600 mg sodium chloride per 24 hr, and among several excellent booklets on this subject, one is prepared for the patient by the American Heart Association. For the treatment of hypertension *per se*, 0.5 Gm sodium chloride constitutes a maximal dietary salt intake, although congestive heart failure and edema *per se* may respond at slightly higher levels. Cation exchange resins, which prevent absorption of dietary sodium, have been used with success to effect decreased sodium absorption from diets containing more than 1 Gm ingested sodium chloride, and the thiazide diuretics are an additional adjunct. Such programs may make meals more palatable for many patients, particularly with the judicious use of one of the salt substitutes. The usual precautions should be observed with the ingestion of cation exchange resins. A low sodium intake may effectively potentiate the effect of other forms of treatment, both surgical and pharmacologic.

Drug Therapy. The rationale for the use of drugs which lower blood pressure is based on the belief that prolonged, marked elevation of systemic arterial pressure is in itself harmful, and may contribute to and hasten the vascular lesions. While this view is regarded with skepticism by some, there can be no question but that there are well-documented cases in which the use of depressor drugs

has aborted or reversed progressive changes of malignant hypertension. Furthermore, there is evidence that patients with severe hypertension whose blood pressure has been effectively lowered by drug therapy over a period of 3 to 4 years may then be maintained on gradually decreasing doses and eventually no drug at all. Since peripheral resistance is the most important of the factors which determine the level of the blood pressure, hypotensive agents, to be effective therapeutically, should act by decreasing resistance rather than by decreasing cardiac output or flow. The introduction of hypotensive agents with varying sites of action has provided the physician with a new approach to medical therapy of hypertension. These drugs, although effective, require of the physician a thorough knowledge of the disease as well as of the agent employed. In Table 245-5 are listed in some detail the important properties of currently available hypotensive agents which the author believes to be worthy of trial when hypotensive therapy is indicated. The use of sodium thiocyanate and nitroprusside, whose actions are similar, has been found by some to be effective in the treatment of hypertensive headache and in lowering of arterial pressure. Because of the necessity for controlling blood levels, however, their use is not widespread.

Of the agents listed in Table 245-5, the ganglionic blocking agents are of extreme and unquestioned potency. Their side effects, however, as well as the need for careful control by frequent blood pressure readings suggest that their use should be relegated to the severer forms of hypertensive vascular disease. The uncertain absorption from the gastrointestinal tract of some of the blocking agents listed in the table constitutes an additional difficulty, although this particular objection appears to be overcome by mecamylamine (Inversine), which is completely absorbed. A significant advance in therapy is represented by the introduction of two agents, guanethidine and bretylium tosylate, whose action is apparently specific for the postganglionic nerve terminals. In effect, the sympathetic impulses are blocked, leaving unopposed parasympathetic action, thus minimizing those undesirable side effects of the ganglionic blockers which are specifically related to parasympathetic blockade. Of these two agents, guanethidine appears to be somewhat preferable because of its more gradual and prolonged action. The widespread use of the thiazide diuretics to potentiate the action of other hypotensive agents is another significant advance. There appears to be little difference between the various substituted thiazides except in the dosage required. One exception to this is the drug *chloralthalidone* (Hygrotron), whose action appears to be more gradual and prolonged than the other thiazides. Sympathetic blockade usually results in a decrease

Table 245-5. DRUGS USED IN THERAPY OF HYPERTENSION

Drug	Site of action	Pharmacodynamics	Dosage*	Special indications	Contraindications	Side effects
Hydralazine (Apresoline)	Central vasodilator + Adrenergic blockade	Vasodilation Increased cardiac output Increased renal blood flow (\pm) Tachycardia	Oral 10-200 mg 4 i d Tolerance ++	As an adjunct with methonium compounds and protoveratrine	Coronary artery disease Peptic ulcer (?)	(1) Arthritis, lupus (2) Illa lache edema, nausea, tachycardia (3) Unopposed cholinergic hyperactivity Rx: (1) Stop drug, (2) anticholinergics, (3) aluminum hydroxide gel
Ganglionic blocking agents	Blocks autonomic transmission at ganglion	Sympathetic and parasympathetic inhibition (orthostatic hypotension with compensatory tachycardia, decreased intestinal motility, etc.)	In moderate to severe hypertension As medical sympathectomy (?)	Coronary artery disease Arteriosclerosis Diabetes Glaucoma Prostatism	(1) Constipation, visual symptoms (2) Urinary retention (3) Impotence Rx: Decrease dose, (1) cathartics, (2) behanachol (Urecholine)
Pentolinium (Ansolysin)	...	Variable absorption from GI tract	Oral 10-70 mg q 6-8 hr SC 2-10 mg q 4-8 hr
Chlorisondamine (Leodal)	Oral 25-100 mg q 12 hr SC 2-10 mg q 8 hr
Mecamylamine (Inversine)	...	Complete absorption	SC 2-10 mg q 8-12 hr	Tremor
Protoveratrine	Stimulates afferent side of vagal reflex	Fall in BP Bradycardia Cerebral resistance Renal resistance Cardiac output unchanged	Oral 0.8-1.5 mg p.c. breakfast plus 0.5 mg p.c. lunch and supper IV 1.5-1.9 mg/kg 1st 4-6 mg/kg q 6-8 hr	Hypertensive encephalopathy Hypertensive pulmonary edema	Intolerance Coronary artery disease (?)	(1) Epigastric oppression, nausea, vomiting, salivation (2) Angina (?) (3) Arrhythmias Rx: Decrease dose, (1) atropine, chlorpromazine (Thorazine), (2) ephedrine for hypotension
Reserpine (Serpasil) (erythraline alkaloid of Rauwolfia serpentina)	Central sedative effect Central inhibition of pressor reflexes Direct peripheral vasular action (?)	Central sedation Mild hypotension Increased intestinal motility Alveoli Full action requires 3-6 days	Oral 0.1-0.5 mg t.i.d. Tolerance \pm	As adjunct to other drugs Alone, in labile neurotic hypertension 2-5 mg daily in hypertensives with renal failure	Elderly depressed patients	(1) Sedation (2) Diarrhea (3) Bradycardia (4) Nightmares (5) Nasal congestion (6) Weight gain, increased appetite (7) Depression Rx: Decrease dose
Phenoxybenzamine (Dibenzyline)	Adrenergic blockade Blocks circulating catecholamines (epinephrine, norepinephrine)	Prevents action of adrenergic mediators (epinephrine, norepinephrine) Alveoli Orthostatic hypotension	Oral 20-120 mg q i d Tolerance ++	As adjunct in hypertension with renal failure	Angina pectoris	(1) Miosis (2) Dry mouth (3) Nasal congestion (4) Impotence (5) Tachycardia Rx: Decrease dose
Bretylium tosylate (Darenthion)	Blocks postganglionic sympathetic fibers	Sympathetic inhibition (orthostatic hypotension) Parasympathetics intact	Oral 0.25-2.0 Gm q i d IV 0.5 mg/kg	Moderate to severe hypertension	Coronary disease Glaucoma Arteriosclerosis Pheochromocytoma	Facial pain, parotitis, impairment of ejaculation, abdominal pain, visual blurring
Guanethidine (Ismelin)	Blocks postganglionic sympathetic fibers	Sympathetic inhibition (orthostatic hypotension) Parasympathetics intact Prolonged effect	Oral 10-80 mg per day IV 0.5 mg/kg	Moderate to severe hypertension	Coronary disease Glaucoma Arteriosclerosis Pheochromocytoma	Facial pain, parotitis, impairment of ejaculation, abdominal pain, visual blurring
Monamine oxidase inhibitors (iproniazid, carboxamid)	Blocks destruction of monamines	Orthostatic hypotension	Oral: iproniazid 50-120 mg per day	Coronary disease	Coronary disease Glaucoma Arteriosclerosis Pheochromocytoma	Flushing, dizziness, confusion
α -Methyl DOPA	Inhibits decarboxylation of aromatic amino acids	Reduction of amino Biosynthesis	Oral 0.75-2.0 Gm t.i.d.	?	?	Sedation, fatigue

* Tolerance ++ indicates a strong likelihood that the dose will eventually need to be increased in order to maintain a given effect

in peripheral resistance, with decreases in cerebral and renal blood flow. Frequently, the cardiac output may fall. For this reason, these agents may be hazardous in cerebral, renal, and coronary vascular disease. Since the blood pressure fall produced by these agents is most marked in the upright position, it may be of value to test their effects upon the electroencephalogram and the electrocardiogram, when the desired fall in blood pressure is achieved by gradual assumption of the upright posture on a tilt table. Decreased sensitivity or tolerance to all these agents has been reported. Because of its effect in increasing renal blood flow, Apresoline may be an important adjunct to the use of the blocking agent. The increase in renal blood flow which occurs with Apresoline, however, is not entirely consistent and results in part from increased cardiac output, in which the renal share of the cardiac output may be actually increased. The production of a syndrome resembling rheumatoid arthritis and disseminated lupus erythematosus with the prolonged use of Apresoline is now well documented. Although, usually, this syndrome is reversible with cessation of therapy, in a few instances persistence of the disease has occurred following cessation of the drug.

The thiazide diuretics potentiate the action of other antihypertensive drugs through their natriuretic action and, possibly, through some direct action on the vasculature. The various substituted thiazides differ in dosage, but are essentially similar in their mode of action. The one exception is chlor-thalidone, whose action is more prolonged, requiring only a single daily dose, varying from 100 to 600 mg.

Dramatic and unquestioned therapeutic results have been obtained with the use of these substances. They are toxic and dangerous in excessive dosage, however, and the margin between the toxic and the therapeutic dose is relatively narrow; hence, all such therapy should be begun in the hospital. The hypotensive agents selected should be administered initially in less than effective dosage and increased slowly, until either the desired therapeutic effect or toxicity supervenes. As with insulin therapy it may be wise, under controlled conditions in the hospital, to familiarize the patient with mild toxic effects so that they can be recognized. Alternate dosage with the initial agent and one of the others, or preferably the potentiation of the depressor effect of the initial agent by the addition of small doses of another drug, may increase the depressor effect while decreasing the side effects inherent in both. Such a combination, too, may minimize the effect of tolerance to either agent. Experience suggests that the concurrent use of two or three of these agents with different sites of action

may be the method of choice. When the patient's dosage has been established in the hospital, he may be seen at less frequent intervals on the outside, and the therapeutic effects may be increased without increasing toxic effects by the addition of a third agent or by the substitution of a new agent for one of the two when tolerance becomes apparent. Potentiation of depressor effect can be achieved also by decreasing the sodium content in the diet. Cessation of therapy should never be abrupt, since dangerous hypertensive rebounds may result. The necessity for carefully controlling the use of these agents carries with it the disadvantage of making the patient drug conscious and blood pressure conscious. Once he has become familiar with the drugs, however, and confident of their therapeutic benefits he may learn to regulate them by taking his own blood pressure in the same manner that an intelligent diabetic regulates his insulin by testing his urine.

The presence of advanced renal failure contraindicates the use of the drugs listed here with the possible exception of small doses of Dibenzylne (10 to 20 mg t.i.d.). This appears to be useful in hypertension with renal failure, possibly through its action on unexcreted pressor amines. In mild renal failure, large doses of reserpine (2 to 5 mg per day) or the combined use of ganglion block and Apresoline may be of value. In properly selected cases, an initial increase in nitrogen retention may be followed later by improvement in renal function, although at considerably decreased blood pressure levels. The sites of action of the various depressor agents are shown schematically in Fig. 245-2.

Surgical Therapy. In the past, interruption of the autonomic pathways by sympathectomy, particularly by the lumbodorsal technique of Smithwick, has produced a convincing decrease in mortality in some severe cases of hypertensive vascular disease. This treatment should probably be reserved until after drug and/or dietary treatment has been tried and failed or been rejected. In this sense, its value has the same relationship to medical therapy as does the surgical treatment of peptic ulcer. Undesirable side effects of sympathectomy are postural hypotension and disturbance of sexual function in the male. Renal failure, cerebral vascular accidents, and congestive heart failure are contraindications. Bilateral total adrenalectomy as a treatment for hypertension is still in the process of evaluation, but may be of value in intractable congestive heart failure with minimal renal functional impairment.

Pyrogens. It has been reported that a prolonged course of high fever induced by the intravenous administration of pyrogens may be effective in some cases of malignant hypertension. This is drastic

FIG. 245-2. Sites of action of the antihypertensive drugs.

treatment for a drastic disease state, and should be carried out only under the supervision of those with some degree of experience in this technique.

Treatment of Hypertensive Encephalopathy. The incidence and clinical picture of hypertensive encephalopathy have been described earlier in this chapter. Although in certain cases hypervolemia may contribute greatly to the abnormality, the common denominator is hypertension due largely to generalized vasospasm. It is rational, therefore, to attempt to lower the diastolic blood pressure by pharmacologic means. This may be done effectively in children, and in a small percentage of young adults, by the intramuscular injection of a 50 per cent solution of magnesium sulfate, in doses of 0.2 ml per kg body weight. This may have to be repeated several times at 4-hr intervals, to keep pressure at satisfactory levels, following which the oral administration of 13 to 30 ml of 50 per cent magnesium sulfate two to three times a day may satisfactorily control the blood pressure. If intravenous injection is necessary, a 3 per cent solution of hydrated magnesium sulfate may be given slowly; 150 mg of the salt per kg of body weight is given over a period of 1 hr. The effects of overdosage (somnolence, respiratory difficulty) may be counteracted by the administration of a 10 per cent so-

lution of calcium gluconate by vein. Oxygen therapy, sedatives, and occasionally, venesection and spinal tap may be useful. Dramatic results have been observed with the use of intravenous or intramuscular protoveratrine or with large doses (2 to 5 mg of parenteral reserpine), and with the continuous drip of an aqueous solution of trimethaphan (Arfonad), a rapidly acting, short-lived ganglionic blocking agent whose effect by this route can be easily controlled by the rate of the drip.

246 ARTERIOSCLEROSIS

William Dock

The pathologist recognizes many types of arteriosclerosis, but clinical disorders due to noninfectious, noninflammatory arterial disease result mainly from atherosclerosis. Even with this condition, pathologic lesions may be widespread and the x-ray may reveal chalk in the aortic knob, the coronary arteries, or the abdominal aorta and its main branches, with not the slightest impairment of bodily function.

The media of the arteries of men and animals show varying degrees of loss of muscular and elastic elements as age advances, and with this the vessels become tortuous and dilated. This change, affecting temporal and splenic arteries and the aorta, may be well advanced by the fourth decade of life. A similar change in the walls of the veins predisposes them to varicosity and to formation of hemorrhoids. But in the arteries neither this medial change nor medial calcification, which is less frequent and occurs later in life, leads to occlusion of the lumen or rupture of the wall. The involutional changes in the media have few or no clinical sequelae.

When age or involution of parenchymal or muscular organs leads to atrophy or, in the brain, to progressive loss of neurones, the vascular bed atrophies and the intima proliferates. A lumen adequate for the needs of the shrunken organ remains, but intimal thickening, free of lipid and physiologically harmless, may lead the unwary pathologist to ascribe atrophy to arteriosclerosis. This is most often said of the cerebrum; in the uterus or ovaries atrophy is accepted as a "normal" concomitant of aging and not blamed on intimal thickening, which is secondary to disuse.

All the changes mentioned above are seen in aged mammals; they are usually bilaterally symmetrical and widely disseminated or diffuse. This contrasts strikingly with the patchy atheromas, lipid-rich intimal thickenings, which occur very rarely in aged wild or domestic animals or even in primitive or very poor populations but are apparent by the age of forty in the bodies of most prosperous people, on the diets usual in North America and Western Europe. As noted by Lober, the process of lipid deposition in the intima of coronary arteries begins with suckling and in our culture

continues throughout life. In rabbits, and in most human populations, lipid deposition ends with weaning, and the deposits are reabsorbed during growth.

Many species of birds and mammals, well fed and growing old in the crowded zoos, have atheromatous arteries, and wild omnivorous baboons have similar lesions. Occlusion of large critical arteries, such as the coronaries and cerebrals, is extremely rare in such instances. In India and in Morocco coronary disease, uncommon even in the prosperous, is very rare in the mass of undernourished people. These differences in incidence in the rich and poor were striking in America before 1920, and also in Russia, where they led Ignatovsky to feed rabbits eggs and butter, and thus initiate the experimental production of atheroma by dietary manipulation, in 1907.

DIET, PLASMA LIPIDS, ATHEROSCLEROSIS, AND THROMBOGENESIS

In the past two decades it has become evident that diets rich in saturated fats (beef, butter, coconut oil) cause an elevation in plasma lipids, including phospholipids, triglycerides, and cholesterol. Unsaturated fats (corn or cottonseed oil, fish oils) and low-fat diets barely adequate to meet caloric needs cause a fall in these lipids. Human populations, shifted from diets rich in saturated fats to those low in these items, show a fall in rate of post-operative thromboembolism and in myocardial infarction. Negroes living on low-fat diets in Uganda and coming to necropsy at ages over forty, had less than 10 per cent the incidence of myocardial scars and infarcts or thrombi in veins and lungs as Negroes of the same age in Missouri, living on American diets rich in pork, butter, and eggs. Rats on atherogenic diets (added cholesterol, bile salt, thiouracil) developed a high rate of coronary and renal artery thrombosis if the dietary fat was butter, a very low incidence if fed the same amount of corn oil.

Diets rich in saturated fat cause the liver to excrete relatively little bile salt, a degradation product derived from cholesterol, and abundant cholesterol, while diets rich in unsaturated fats have the reverse effect. Cholesterol is constantly synthesized by vertebrates, but the amount secreted in bile and reabsorbed from the gut has a large influence on the plasma lipid level. Because diets low in animal fat, rich in vegetable oil lead to secretion of abundant cholate, which has a detergent-like action and renders cholesterol more soluble, cholesterol stones rarely form in those adhering to such diets. In populations living on diets rich in animal fat, as in North America, there is a variation in plasma cholesterol, in healthy adults, from 150 mg per 100

ml to above 600. Levels over 300 usually indicate familial hyperlipemia, with high triglyceride levels in most cases, or pure familial hypercholesterolemia. Such patients, on low-fat cholesterol-free diets, have daily biliary excretion of cholesterol higher than those with plasma cholesterol levels under 250 mg per 100 ml. Fortunately, many of the hyperlipemias show a striking drop in all lipid fractions on diets with a liberal intake of polyunsaturated fatty acids.

Cholesterol added to diets merely augments the effect of the saturated fats in some species, but in rabbits and chicks cholesterol alone, added to a diet rich in unsaturated fat, raises plasma lipid and causes rapid atherogenesis. Since most of the cholesterol-rich foods (brain, egg yolk, butter) also are rich in saturated fats, the "low cholesterol diet" emphasized by some physicians before 1950 was also a diet low in saturated fat and in many patients did actually reduce plasma lipid levels. Today, substitution of corn or cottonseed oil for butter, and fish for beef and pork, is usually recommended and has proved more effective than low-fat diets.

While diet and elevated levels of cholesterol and triglyceride are of established importance both in atherogenesis and thrombogenesis, many remarkable deviations from a simple diet \rightarrow plasma lipid \rightarrow vascular disease pattern remain unexplained. Thus baboons develop atheromas with blood cholesterol levels of 40 to 100 mg per 100 ml, rabbits only when the level is over 150, dogs only when it is over 400 mg per 100 ml. The α -lipoproteins of the plasma stabilize or hold in solution triglyceride while β -lipoproteins, poorer in lecithin and phosphorus, appear to form atheromas. Dog plasma has a relatively low ratio of β - to α -lipoprotein. In man atheromas form slowly or not at all at levels under 160 mg per 100 ml, but they form more rapidly in infants and in adolescent boys, and in Negro but not in white girls, than in senescent people whose blood cholesterol levels are higher. Thrombogenesis is, of course, very rare in infants and adolescents, but common in mature people living on diets rich in animal fat. Hyperlipemia accelerates clotting, but only to a very slight degree. It does, however, significantly retard fibrinolysis, and its effect in thrombogenesis, in veins or diseased arteries, seems mainly based on interference with clot lysis.

Other known factors in raising plasma lipids are intense emotion, adrenal corticosteroid, ACTH, and fat mobilizing hormone of hypophyseal origin. Epinephrine also acts, in part through stimulating release of these factors, to raise levels of unesterified fatty acid, triglyceride, and cholesterol in the blood. Osler and others emphasized the effect of "lives of high tension" in hastening vascular disease. The effects of intense emotion in raising plasma cholesterol were reported from Walter Cannon's labora-

tory in 1930, and recent workers have demonstrated that emotional burden or response to competition raises plasma lipid and shortens clotting time. On the other hand, muscular exercise greatly increases fat combustion and lowers plasma lipid levels as do elevated levels of thyroid hormone, although the latter augments epinephrine action and emotional response to the environment.

Heparin activates or liberates lipoprotein lipase and hastens the solution of the chylomicra which make plasma hazy after a high-fat meal. Lipoprotein lipase levels, and plasma heparin levels, are reported to decline in the aging human, and to be lower in those with coronary disease than in control subjects of the same age. Albumin serves as carrier for the fats released by lipase, and in hypoalbuminemia this mechanism breaks down, leading to hyperlipemia and hypercholesterolemia. In obstructive jaundice, plasma lipids rise to extremely high levels, but the plasma is clear because of the high level of α -lipoprotein, rich in lecithin. The clear icteric plasma becomes cloudy with fat droplets if lecithinase is added. Neither atherogenesis nor thrombogenesis is initiated by the intense hyperlipemia caused by obstructive jaundice, but many xanthomas may appear in the skin.

Diabetes includes several types of disturbed metabolism. Pancreatic insufficiency, in rabbits and probably in men, does not greatly alter atherogenesis. But the more common type of diabetes, with intact or hypertrophied pancreatic islets, does cause hyperlipemia. Even when subclinical in severity, it may lead to precocious atherosclerosis, and many cases, well-controlled by insulin, develop remarkable arteriolar atheromas, in the kidney and retina, as well as clinical evidence of coronary disease or impaired circulation in the legs. These lesions developed rapidly when diets rich in animal fat were used in juvenile diabetics. They can be arrested or reversed by diets low in animal fat.

White men are far more prone to coronary occlusion before the age of sixty than white women, and white boys show far more rapid lipid disposition in the coronary arteries and aorta during adolescence than do white girls. In American Negroes there is no such sex difference. The ratio of β - to α -lipoprotein in white males is higher than in females, and can be reduced by estrogen therapy. This does not occur in myxedematous patients, and the effects of androgens, estrogens, and thyroid hormone seem interrelated. It is also known that adolescent white boys in America greatly increase their intake of animal fat during adolescence, while girls do not. Finally, there are anatomic differences in the intima of the coronary arteries of white males and females, even at birth, which may contribute to the more rapid evolution of obstructive disease in young men.

HYDRAULIC AND ANATOMIC FACTORS IN ATHEROGENESIS

One of the most striking features of atherosclerosis is the spotty distribution of lesions and the variation in severity in different vessels in different bodies. One person may have extensive, almost xanthoma-like disease of the coronary arteries in the epicardial fat, with none in deeper muscular branches, and only a few small plaques in the abdominal aorta. Another may have severe ulcerated, thrombus-covered plaques in the abdominal aorta and iliac artery, with rare and small coronary lesions. Or the favored site may be the internal carotids, the basilar and cerebral arteries, or the leg vessels below the popliteals. The rarity of pulmonary arterial lesions, except with pulmonic hypertension, and of disease of branches of the brachial arteries, as compared with that in femoral branches indicates that high intraarterial pressure as well as hydraulic stresses at bifurcations favor plaque formation. In animals and man, hypertension accelerates atherogenesis. Vessels damaged by syphilis, tuberculous meningitis, or pericarditis also develop severe lesions in Americans, but not in poor Chinese on diets of millet and soybeans. The intimal struts of loose connective tissue with longitudinal muscle fibers, peculiar to the coronary arteries and larger in males than females, seem to be particularly important in predisposing these vessels to atheroma. Because these struts or cushions of thick intima vary greatly in individuals, it is not surprising that some of us die of coronary disease with few other lesions, while others, with marked hypercholesterolemia, only show aortic lesions at seventy or eighty. It is for this reason that "coronary indices," based on plasma lipid levels, are of little value in individual cases, while family histories of frequent cerebral or coronary accidents correlate well with higher risk of similar lesions in the offspring.

One may summarize the human problem of pathogenesis by saying that, in countries with undernourished populations, atherosclerosis is a disease of the rich and well-fed; in well-nourished countries, it favors men and women competing most fiercely for status. Yet, in some fields of business (telephone, insurance), coronary rates are lowest in executives, highest among the clerks.

Tobacco, which acts much like epinephrine, accelerates atherosclerosis, but part of the higher death rate from coronary disease among smokers may be due to the fact that tense competitive people seek sedation from smoking. Malnutrition plus constant alcoholic intake damages cholesterol synthesis and spares the arteries, but acute alcoholism or even the daily intake of one or two ounces of alcohol increases hepatic synthesis and raises plasma

levels of cholesterol and fat. When it is recalled that eggs and milk, like alcohol and nicotine, are not biologically normal foods for weaned mammals, it can be seen that our present knowledge confirms Osler's statement: "Angiosclerosis is the Nemesis through which Nature exacts retributive justice for the transgression of her laws."

RECOGNITION AND MANAGEMENT OF ARTERIOSCLEROSIS

Necropsy showed that 50 per cent of American soldiers, dying of wounds at an average age of twenty-two years, had grossly apparent atherosclerosis. By age fifty this rises to over ninety per cent, and nearly 50 per cent have marked narrowing of one or more main coronary arteries. The physician's problem is not to diagnose or exclude arteriosclerosis but to determine which patients have experienced or are seriously threatened by occlusion of vessels capable of causing disability or death.

When this disease was regarded as a relentlessly advancing degeneration, for which there was no remedy, the diagnosis merely added a new emotional burden of frustration and fear. This accelerated the progress of the disease. Now that many physicians and laymen accept the idea that atherosclerosis and thrombogenesis may be halted by change in way of life, by drugs that alter plasma lipids and by others that retard intravascular clotting, the diagnosis carries a different meaning. Because many public figures are known to be active and effective years after serious vascular accidents, the need for reassurance is lessened and the effectiveness of sound medical advice is much greater than it was in 1955, when most physicians and textbooks began to reflect the knowledge gained since Ignatovsky's experiments in 1907.

Significant arteriosclerosis is diagnosed by excluding embolic, arteritic, or congenital vascular lesions in patients with such disorders as angina pectoris, myocardial infarction, hemiplegia, intermittent claudication, and other focal evidence of tissue ischemia, or by observing retinal hemorrhage or exudate without embolic or hematologic basis. Roentgen study may reveal chalk, or palpation of peripheral vessels may demonstrate calcification in arteries when none of the above disorders exists. Diabetes, hypertension, or very high plasma lipid levels without jaundice may indicate unusual risk of vascular occlusion in individuals with faultless organic function. Present-day roentgen angiography, with contrast media, permits accurate study of the extent and severity of vascular lesions due to arteriosclerosis and has proved invaluable in the study of cerebral disease, aortic or renal arterial obstruction, and coronary sclerosis. These studies

carry some risk, they are expensive and uncomfortable, so that they are used only when clinical findings suggest that surgical intervention to improve function should be considered.

Renal arterial obstruction causing hypertension, like coronary disease, may be the only significant arterial lesion. Such lesions may be due to trauma, but most of them comprise atheromas. Careful abdominal auscultation in a very quiet room may reveal bruits arising in renal stenosis, and separate functional study of both kidneys may indicate unilateral renal disease, probably vascular. Angiography is usually of critical value in identifying these lesions.

Some pathologists believe that renal arteriolar lesions precede and cause arterial hypertension in most cases now called essential or familial hypertension. This is difficult to accept in those persons whose hypertension remains benign, with no retinal or renal damage, after decades. Unexplained heart failure should not be diagnosed as coronary disease or "arteriosclerotic heart," nor unexplained hypertension labeled "renal arteriosclerosis," nor loss of memory or personality change accepted as "cerebral arteriosclerosis." Other causes must be carefully excluded before arterial obstruction is blamed, and in doubtful cases roentgen study may be necessary to confirm this impression, in cases where endarterectomy offers possible relief of ischemic pain, recurrent paralysis, or renal hypertension.

Medical management, aimed to establish collateral circulation to the legs or the myocardium, and to retard or reverse occlusive disease, includes regular quiet exercise as well as diets low in animal fat, drugs such as nicotinic acid, and the newer synthetic drugs which impair cholesterol synthesis, heparin which affects both lipid levels and coagulation, and agents which impair prothrombin production. Because of expense and inconvenience, heparin is rarely used over long periods, but coumarin analogues in doses adequate to hold prothrombin at one-quarter or less of its normal level have been widely used for years. Claims for its value often cite "control" death rates in angina or healed myocardial infarction which are much higher than those reported in large series of untreated patients in most clinics. Controlled studies, in Norway and England, indicate very modest success for such a preventive antiprothrombin regimen. Patients are greatly reassured and anxiety is reduced when physicians treat them with confidence, with either drugs or diet, so it is unwise to advise discontinuing such a regimen when a patient has accepted it.

The conservative, or Hippocratic, management is to persuade patients to accept a sane diet and way of life, with minimal use of tobacco, alcohol, dairy fat, eggs, and stall-fed beef or pork, and

minimal use of drugs. Page's experience indicates that, in most men, vegetable oil diets are more effective than low-fat diets in lowering triglyceride levels, but in women this is less often the case. For those who prefer expensive substitutes for familiar foods, one may obtain in England all sorts of dairy foods made from skim milk and corn oil; presumably the larger American market will eventually be supplied by the less enterprising dairy industry here. Margarines are now marketed with corn or cottonseed oil base. There is so little difference in the hydrogenated fat added to solidify various margarines advertised for lowering cholesterol, that taste and cost rather than relative unsaturation should determine the choice of these.

When cholesterol levels remain over 200 mg per 100 ml on such a regimen, 2 to 6 Gm of nicotinic acid daily, the cholesterol depressant triparanol (MER-29), 200 mg daily, dextrothyroxin, 2 to 8 mg or USP thyroid extract, 60 to 180 mg daily, may prove effective. All the drugs have maximal effect when a proper diet is used, but all may be of value in those who cannot or will not diet. Other combinations prove effective, using two agents, each in doses below levels which evoke unwanted effects. As therapy may be needed for years or decades, the physician must determine by trial in each patient which effective drug or combination is least troublesome and least expensive. The flush due to nicotinic acid at the start of treatment is accepted when patients feel that this is good to maintain a youthful skin, but peptic ulcer, gout, and glycosuria, though rare, may bar use of this agent, which lowers triglycerides as well as cholesterol. Triparanol may cause indigestion or other unacceptable symptoms. Thyroid extract and, even more often, dextrothyroxin may be very effective in altering lipid levels at doses which cause no rise in heat production and no angina even in coronary disease. Both cause more symptoms at high dosage in myxedematous than in euthyroid subjects.

With no change in way of life, such famous physicians as John Hunter, James MacKenzie, and Frank N. Wilson lived active lives for nearly two decades after myocardial infarction, so that one hesitates to start on perennial therapy bold patients who are more stressed by restrictions or drugs than by the risk of the untreated disorder. Some men, who are intolerant of the brief "sun-burned" feeling which occurs at the start of nicotinic acid therapy, unhesitatingly face the pain of thoracotomy and the relatively high mortality (over 25 per cent) of the pioneer coronary endarterectomies. Many other patients are delighted to accept any inconvenience in order to diminish the risk of progressive vascular disease, so long as they can avoid operation. Osler's dictum, "It is often more important to know what sort of patient has a disease than to know what sort

of disease a patient has," applies with unusual force to the management of patients with significant arteriosclerotic lesions.

247 DISEASES OF THE AORTA

Victor A. McKusick

DISSECTING ANEURYSM OF THE AORTA

Cystic Medial Necrosis. This is the most frequent morphologic substrate of dissecting aneurysm. It is not the only structural change which can lead to dissection, and conversely it can produce clinical manifestations in the absence of dissection. Cystic medial necrosis appears to be a nonspecific change in the aorta in response to hemodynamic stresses. The frequency with which it is found at autopsy increases with the age of the group studied. (The age distribution of cases of dissecting aneurysm is similar.) Its anatomic distribution is also characteristic, being most marked in the ascending aorta and decreasing progressively as one passes farther from the aortic valve, especially beyond the vessels which branch at the aortic arch. Hypertension accelerates the development of cystic medial necrosis. Furthermore, cystic medial necrosis and dissecting aneurysm are rather frequent complications of coarcta-

tion of the aorta. The hemodynamic changes produced by aortic stenosis and regurgitation accelerate the development of cystic medial necrosis in the ascending aorta. In the genetically defective aorta—that of the Marfan syndrome (p. 1884) is the only clear example one can cite—the ordinary hemodynamic stresses lead to early development of cystic medial necrosis, especially in the ascending aorta, with progressive dilation and/or dissecting aneurysm. (In all dissecting aneurysm, the intimal rent occurs most often in the ascending aorta.) All these features suggest that cystic medial necrosis is a relatively nonspecific morphologic expression of "wearing-out" of the aorta in response to hemodynamic stress. The stress to which the ascending aorta is particularly subject is repetitive expansile pulsation. With each heart beat the ascending aorta is subjected to greater expansile pulsation than any other part of the aorta, especially more than that beyond the aortic arch.

Syphilitic aortitis does not lead to dissection nor does atherosclerosis *per se*.

Dissecting aneurysm occurs more commonly in men. Under the age of forty years, approximately half the instances of dissecting aneurysm in women occur in relation to pregnancy. Hormonal changes associated with pregnancy seem to be responsible for effects on connective tissues, including those of the aorta.

Usually from an intimal rent in the ascending aorta, dissection extends proximally to the aortic ring and distally for a variable distance. (Occasionally an intimal rent is absent. Bleeding into the media from vasa vasorum is obviously important in such cases and probably is important in the initiation of most cases. Hence the synonyms for dissecting aneurysm: medial hematoma and dissecting hematoma of the aorta.) "Reentry" may take place at some site, such as just beyond the left subclavian orifice or in the abdominal aorta, with creation of a "double barrel aorta." Prognosis is better in such cases. The dissection may extend for a considerable distance into one or several of the branches of the aorta, from the coronary arteries to the iliac arteries. The proximal dissection may distort the aortic ring and result in aortic regurgitation. (Cystic medial necrosis antedating the dissection may have resulted in dilation of the sinuses of Valsalva and aortic regurgitation.) Rupture of the aorta into the pericardial or pleural cavity occurs in a majority of cases, although other sites of rupture such as the transverse portion of the duodenum are occasionally observed. Rupture into the pericardial sac is not surprising since the pericardial reflections extend high on the ascending aorta in many persons.

The clinical manifestations of dissecting aneurysm can be classified as follows:

1. Pain

2. Aortic regurgitation
3. Interference with the blood supply through branches of the aorta
4. X-ray evidence of progressive widening of the aorta
5. Rupture of the aorta

In addition, tissue destruction may be of sufficient proportions to produce mild fever, leukocytosis, and elevation of sedimentation rate.

The pain of dissecting aneurysm is sometimes described as tearing in quality. It is questionable that its quality is truly different from that of coronary occlusion. Characteristically it attains peak intensity very shortly after onset. It may involve the anterior chest, back, lumbar area, or abdomen, sometimes in a progression. Dissecting aneurysm may occur, however, with little or nothing the patient describes as pain. The blood pressure may drop precipitously during the dissection, but maintenance of hypertension or increased blood pressure in response to the pain is often the finding.

The most frequently observed evidence of disturbance at the orifices of the branches is discrepancy in the pulses and blood pressure readings in the arms. Asymmetrical diminution in these may occur. The same observations may be made in the carotid and femoral vessels. Myocardial infarction or changes of myocardial ischemia, neurologic signs from interference with cerebral and/or spinal blood flow, intestinal symptoms, and hematuria may occur.

Rupture of the aorta is, of course, usually fatal. However, in rare instances leakage into the pericardial cavity may be interrupted and the patient survive for months or even years. The chest pain, together with a pericardial friction rub, can indicate the presence of leaking dissecting aneurysm hours before the leak proceeds to the point of producing cardiac tamponade.

In the differential diagnosis of dissecting aneurysm, myocardial infarction and pulmonary embolus present the greatest problems. Pain reaching a rapid peak of intensity, especially if followed within minutes or hours by signs of arterial occlusion, favors the diagnosis of dissecting aneurysm. Unconsciousness may result from involvement of the cephalic trunks in the dissection and is unusual in myocardial infarction in the absence of severe hypotension or arrhythmia. The maintenance of arterial hypertension favors dissecting aneurysm, although profound hypotension can occur in both dissection and myocardial infarction.

Only a few cases survive more than a few days after an acute dissection. Most of the survivors succumb to rupture of the aorta or other complications within a year. Surgical treatment is in its infancy. The ingenuity of the surgeon will undoubtedly permit, in the future, correction of the aortic lesion in

a larger proportion of cases. Pharmacologic hypotension in those cases with maintained hypertension during the acute dissection has a rational place in treatment of the early stages.

Cystic medial necrosis sometimes results in aneurysm, usually of the ascending aorta, without dissection. The clinical behavior resembles syphilitic aneurysm in many respects. In other cases, aortic regurgitation is the main and presenting problem. Surgical treatment has been successful in some of these instances.

SYPHILITIC AORTITIS

Syphilitic involvement is limited largely to the thoracic aorta, particularly the ascending aorta. Syphilitic cardiovascular disease rarely occurs in persons who have had syphilis for less than 10 years or in those who received even a moderate amount of antisyphilitic treatment in the early stage of the infection. On the other hand, so great is the predilection of *Treponema pallidum* for the aorta that a majority of untreated cases have involvement of that vessel. Fortunately, the frequency of syphilitic cardiovascular disease has decreased markedly in the last decade.

The predominant localization of syphilitic change to the ascending aorta may be the result of the combination of the particular hemodynamic stress (see Cystic Medial Necrosis, p. 1365) with the medial damage by the treponemal infection. Other explanations are probably less satisfactory.

Aortic regurgitation, fusiform aneurysm, or sacular aneurysm can result. Syphilitic aortitis uncomplicated by any one of these three may betray its presence by a change in the quality of the aortic second sound usually referred to as "tambouric" (scarcely a pathognomonic sign, however) and by the presence of intimal, shell-like calcification in the first part of the ascending aorta. In some cases this calcification even extends proximally to outline the sinuses of Valsalva. Atherosclerosis alone usually does not produce calcification in the first part of the ascending aorta. The primary lesion of syphilitic aortitis is medial, but intimal atherosclerosis is accelerated by the damage to the media. Occlusive change in the ostia of branch arteries, such as the coronaries with production of angina pectoris or the aortic arch vessels with production of the aortic arch syndrome (p. 1367), occurs by a similar mechanism.

Syphilitic aneurysms occur with diminishing frequency from the ascending aorta distally toward the abdominal aorta. They may be single or multiple, diffuse or sharply localized, fusiform or sacular, smooth-walled or thrombus-filled. Symptoms are likely to be due to compression (e.g., of the trachea, pulmonary artery, or superior vena cava) or erosion

(e.g., of the sternum or vertebral column). Rupture into the superior vena cava or pulmonary artery may occur and the patient survive for some time, with dramatic physical findings. Sudden death may result from external rupture or rupture into the tracheobronchial tree, pericardium, esophagus, etc. Happily, with improved public health control of syphilis and with better treatment, syphilitic aneurysm may soon become a matter of no particular concern to the clinician.

There has never been convincing evidence that specific treatment given after the development of clinical signs of cardiovascular syphilis prolongs life. There is evidence that aortic regurgitation is more frequent in syphilitic aortitis than previously thought; however, the prognosis in these patients is better than previously realized.

Herxheimer reactions following closely after the administration of penicillin have been observed in early syphilis in which fever may occur and in central nervous system syphilis in which fever and aggravation of mental disturbances may be seen. Although the occurrence (after penicillin treatment) of Herxheimer reactions involving the coronary ostia remains to be established, it is probably wise in a patient with cardiovascular syphilis and angina pectoris or electrocardiographic signs of myocardial ischemia to improve the myocardial status as much as possible before antisyphilitic therapy and to institute such therapy only under conditions of optimal rest and observation.

Surgical therapy for syphilitic aneurysms has made outstanding advances.

ARTERIOSCLEROTIC ANEURYSMS

Arteriosclerotic aneurysms occur most frequently, although not exclusively, in the abdominal aorta, especially in that portion between the ostia of the renal arteries and the bifurcation. The patients are usually men in the sixth and seventh decade of life or older. Both dilatation and buckling of the aorta are usually involved, and the buckling is usually predominantly to the left.

Manifestations include primarily pain in the back or anterior abdomen and a pulsatile abdominal mass which usually presents in the epigastrium. (As projected on the anterior abdominal wall, the bifurcation lies at approximately the level of the umbilicus.) The patient may discover that the knee-elbow position relieves the pain. The diagnosis may be obvious from ordinary x-ray films of the abdomen if an eggshell-like or other calcification outlines the aneurysm. Aortograms can make the definitive anatomic diagnosis.

Rupture of arteriosclerotic aneurysms is frequently the mechanism of death. Rupture is likely to begin in the ulceration of an atheromatous

plaque. There is usually no more than short medial dissection. Rupture may result in the rapid development of a mass in the left flank. The hematoma may dissect retroperitoneally into the groin and produce manifestations simulating incarcerated inguinal hernia. Rupture into the duodenum, another indication of the high location of these aneurysms, may occur.

Arteriosclerotic aneurysm of the abdominal aorta has been treated surgically with success. Resection of the affected portion and replacement with aortic homograft or a synthetic prosthesis has been performed. In the minority of cases in which the renal arteries and higher branches of the aorta are involved in the wall of the aneurysm, modifications of the basic procedure are necessary.

AORTIC ARCH SYNDROMES

(Pulseless Disease, Young Female Syndrome, Takayasu Syndrome, Reverse Coarctation)

Slowly progressive change can lead to partial or total obliteration of the major branches of the aortic arch. Intimal atherosclerosis alone can produce at least a partial aortic arch syndrome, and it often collaborates with other factors such as syphilis and trauma in producing obliteration. Severe trauma to the upper chest, especially if the neck is extended, may rupture elements of the media in the region of the ostia of the arch branches and thus lay the groundwork for progressive intimal atherosclerosis at these sites. An inadequately understood progressive disorder occurs especially in young females for which reason the designation *young female syndrome* has been used. Histopathologically these cases have been characterized by collections of chronic inflammatory cells, including giant cells. In this disorder the obliteration of major branches is especially likely to be complete, and the designation *pulseless disease* is particularly appropriate. Because of the absence of pulses in the upper part of the body with normal femoral pulses, the term *reverse coarctation* has also been applied to this group of conditions.

In addition to the loss of palpable pulses, clinical manifestations include easy fatigability of the arms, atrophy of the muscles and other soft tissues of the face, necrosis of the cartilaginous nasal septum, and cataract. Systolic murmurs may be heard just above and below the clavicles if the occlusion is partial. If the pressure proximal to the obstruction is at all times in the cardiac cycle higher than that distal to the obstruction, a continuous murmur simulating that of patent ductus arteriosus may be heard in the same area. Syncope attacks, especially with quiet standing after exercise, also occur.

Surgical replacement of the aortic arch has been performed in a few cases and will undoubtedly become increasingly feasible in the future.

THROMBOTIC OBLITERATION OF THE BIFURCATION OF THE AORTA (Leriche Syndrome)

The bifurcation of the aorta is, like the bifurcation of the common carotid artery and the coronary arteries, an Achilles heel of the arterial tree as far as the development of atherosclerosis is concerned. Slowly progressive thrombosis at the bifurcation can result in complete obliteration of the aorta. The patients are usually men and may be as young as the fourth decade. Some of the patients have hypercholesterolemia. The same clinical picture can result from saddle embolism of the bifurcation, as in mitral valve disease or myocardial infarction, if the patient survives the acute episode and is not operated on early.

The clinical manifestations of the Leriche syndrome are (1) intermittent claudication, with pain in the low back or gluteal area which may be mistaken for "sciatica"; (2) loss of the ability to maintain a stable erection, because of the poor blood supply to the penis; (3) globose, that is, symmetrical, atrophy of the legs, which may be difficult to appreciate because of its symmetry; and (4) absence of both femoral pulses. Most of the patients have manifestations of atherosclerosis elsewhere—cerebral, coronary, aortic arch ostia—and hypertension is frequent. Differentiation from coarctation of the aorta is afforded by feeling an aortic pulse in the epigastrium and by the absence of certain other signs of coarctation such as notching of the ribs and dilated collateral vessels over the thorax. Lateral x-ray views of the lumbar spine may reveal basket-like or other calcification in the region of the bifurcation. Aortograms can make the diagnosis definite.

Surgical replacement of the aortic bifurcation with homograft or synthetic prosthesis has been attended with considerable success.

TRAUMA OF THE AORTA

Penetrating wounds of the chest may be rapidly fatal because of puncture of the aorta. Nonpenetrating trauma to the chest, most commonly the steering wheel injuries in automobile accidents, may lead to rupture of the aorta. In over one-third of cases such rupture is just beyond the mouth of the left subclavian artery. If the victim survives the acute tear, a false aneurysm may result at this site. Such aneurysms are susceptible to surgical resection. As mentioned elsewhere (p. 1367), progressive obliteration of ostia at the aortic arch with production of the aortic arch syndrome may be a late complication of trauma of particular type.

AORTIC SINUS ANEURYSM

Aneurysms may occur in the sinuses of Valsalva from syphilis, idiopathic cystic medial necrosis, or a presumably congenital (ill-understood) basis. Rupture into the right atrium or right ventricle may occur. Successful surgical closure has been effected in such cases. Aneurysm of the aortic sinuses usually with symmetric involvement of all three sinuses occurs as a characteristic feature of the Marfan syndrome. Such aneurysms rarely if ever rupture into the right heart.

UNUSUAL FORMS OF AORTITIS

Unusual forms of aortitis include mycotic aneurysm, such as that produced by aortic tuberculosis, temporal arteritis with aortic involvement, and granulomatous aortitis of the proximal few centimeters in ankylosing spondylitis.

Coarctation and other congenital anomalies of the aorta are discussed elsewhere (pp. 1430 and 1432).

248 VASCULAR DISEASE OF THE EXTREMITIES

Eugene A. Stead, Jr.

SYMPTOMS AND SIGNS

One should suspect peripheral vascular disease in a patient with the following symptoms and signs.

1. Pain in an extremity which is induced by exercise and relieved by rest; pain which is influenced by posture, is localized to one digit, is unilateral, or is paroxysmal
2. Impaired pulsations of peripheral arteries
3. Abnormal color of the skin, particularly when affected by raising or lowering of the part
4. Gangrene, ulceration, impaired nail growth, scleroderma, excessive calluses, or paronychia infections
5. Abnormal pulsations, enlarged veins, or edema

6. Unusual warmth or coldness
7. Swelling, atrophy, or difference in length of extremities
8. Auscultatory evidence of arteriovenous fistula
9. Localized systolic murmur over a large peripheral artery
10. Cyanosis of digits when immersed in cold water
11. Peripheral neuritis

If the above signs and symptoms are absent, peripheral vascular disease need not be considered.

The arteries, capillaries, veins, and lymph vessels may be involved separately or in varying combinations. The disturbances may be due to organic disease of the vessels or abnormal constriction or dilatation caused by dysfunction of the autonomic nervous system.

DISTURBANCES IN ARTERIAL FUNCTION

Special Points in History and Physical Examination. Arterial insufficiency causes disturbances in nutrition to the part. The following points in the history and examination are to be noted:

Sensitivity to Cold with Blanching or Cyanosis of Digits. On examination, the part with arterial insufficiency may be colder than the corresponding part of the opposite extremity.

Muscle and Nerve Ischemia. Pain which develops in the muscles of the foot or calf on walking and which disappears on rest is called *intermittent claudication*. If exercise is continued after the pain appears, the muscles may become tender. In more severe ischemia of the leg, pain may occur at rest and be relieved by dependency. The pain of ischemic neuritis is severe and diffuse, with severe exacerbations. Sharp shooting pains may dart through the entire extremity. The acute paroxysms are apt to occur at night.

State of Peripheral Vessels. Presence or absence of femoral, popliteal, dorsalis pedis, and posterior tibial pulses is noted. Gangrene of the digits may occur without disturbances in these pulses. In the absence of a palpable pulse, the skin may show no evidence of malnutrition.

Murmurs over Peripheral Vessels. Pistol shot sounds are heard over the major vessels when the diastolic pressure is low and the stroke output high. Localized systolic murmurs are heard over areas of narrowing produced either by disease of the blood vessel or by external pressure. When the vessel is narrowed, the local points of stenosis produce a murmur similar to that heard in aortic stenosis. If the diastolic pressure below the point of narrowing is low, either because of poor collateral circulation or because of wide vasodilatation produced by exercise, a continuous murmur may be heard. With this exception and that of venous hums, continuous

murmurs are commonly the result of an arteriovenous communication.

Blanching on Elevation; Redness and Cyanosis on Dependency. On elevation to a 90° angle, the part becomes pale and at times white. The extent of the pallor indicates the extent of the arterial insufficiency. If only the toes or a part of a toe is involved, the pallor is limited to the ischemic area. The color returns slowly on lowering the part to heart level. The pallor occurs on elevation because the blood in the capillaries and venules drains out of the part by gravity, and because the effective arterial pressure is lowered by having to overcome the hydrostatic force of a column of blood extending from the heart level to the elevated part. Some pallor on elevation will occur in a normal foot, but the pallor of arterial insufficiency is much more marked.

When the part hangs down, the blood flow is increased temporarily over the horizontal position because the hydrostatic pressure is added to the pressure created by the heart. The increase in arterial pressure is effective until the veins fill. Then it is opposed by an equal column of blood on the venous side, and the pressure differential between artery and vein returns approximately to the differential present in the horizontal position. The minute vessels of the part, being in a state of chronic injury because of an inadequate circulation, are dilated. When these vessels first fill, they are red. Varying degrees of cyanosis gradually develop because of the slow blood flow.

Atrophic Changes in Skin and Edema. The skin becomes thin and atrophic. Slight edema with loss of normal wrinkles is common. If the patient keeps the foot dependent day and night to relieve pain, pitting edema may develop from the combination of a high capillary pressure from dependency and the damaged state of the capillaries caused by ischemia.

Gangrene

Infection. Devitalized tissue offers a good place for infection to spread. When peripheral neuritis is present, infection may be more prominent than ischemia. Osteomyelitis may occur.

Neurologic Findings. Peripheral neuritis is a common complication of diabetes. Periarthritis nodosa and arteriosclerosis may cause neuritis because of the interference with the blood supply to the nerves. In periarthritis, motor paralysis as well as sensory loss and pain is common.

Occupation. There may be a history of unusual exposure to cold and dampness. Use of the pneumatic hammer has been said to cause Raynaud's phenomenon.

Determination of Cause of Arterial Circulatory Insufficiency. If the findings are those of arterial circulatory insufficiency, it must be determined

whether the insufficiency results (1) from occlusive disease entirely, (2) from overactivity of the sympathetic nervous system, (3) from abnormal reaction of the blood vessels to cold, (4) from the effect of cold agglutinins or cryoglobulins on the physical state of the blood, or (5) from a combination of mechanisms.

The constrictor effect of the autonomic nervous system may be removed by paravertebral block of the appropriate sympathetic ganglion with procaine or by release of vasoconstrictor tone by body heating. In either method, the patient, with body exposed, is placed in a cool room (temperature 18 to 20°C). The body temperature may be raised by enclosing the trunk in a heating cabinet or by immersing two uninvolved limbs in water baths at 43°C for 40 min. When vasodilatation is produced in the upper extremities by body warming or by blocking of the sympathetic ganglion, the temperature of the digits rises rapidly to between 30.5 and 33°C. If the temperature rises to between 27 and 29°C, there is moderate organic vascular disease. If no rise occurs or if the temperature falls, advanced local arterial disease is present. Body warming is the simplest and most effective method of relieving vasoconstrictor tone in the upper extremities. It fails occasionally in the lower extremities. Therefore, if full vasodilatation does not occur, paravertebral block is indicated in the lower extremities.

ORGANIC OBSTRUCTION

Balance between Vessel Obstruction and Vessel Formation. Obstruction of a large artery is a strong stimulus for new vessel formation and collateral circulation. The symptoms produced represent the result of the balance between these two processes. Complete obstruction of the aorta below the renal vessels which occurs slowly may produce no symptoms or the picture of impotence and thigh claudication. The extremities may appear normally nourished. When skin involvement becomes marked, little blood vessels are usually thrombosed. This may be primary small vessel endarteritis as in diabetes, or it may be secondary small vessel thrombosis secondary to occlusions higher up. Gangrene with normal pedal pulses indicates small vessel disease. Intermittent claudication with normal appearing vessels and absent popliteal or femoral pulses suggests larger vessel obstruction, which is frequently segmental.

Peripheral Arteriosclerosis. The etiology and pathology of peripheral arteriosclerosis have been discussed in Chap. 246. The history and physical findings are those of arterial insufficiency. The diagnosis is based on the following factors:

1. Age of the patient. It usually occurs after fifty years of age.
 2. Sex. Males are more commonly affected than females.
 3. Diabetes. The incidence of arteriosclerosis is increased in patients with diabetes.
 4. Evidence of arteriosclerosis is usually present bilaterally, although the symptoms may be unilateral.
 5. There are no symptoms of arterial disease in the upper extremities.
 6. The arteries, as seen by x-ray, are frequently calcified.
 7. In patients with diabetes, the small vessels may be occluded, although the larger vessels are only moderately diseased. Local gangrene of the skin of the toes may occur, even though the rest of the foot is warm.
 8. In patients with diabetes, neuropathy is common.
- Thromboangiitis Obliterans.** This condition was described by Buerger in 1908 as an obliterative vascular disease affecting chiefly the peripheral arteries and veins of Jewish males in early adult life. The disease involved primarily the blood vessels of the extremities, beginning in medium- and small-sized arteries. Veins were involved less commonly. The lesion was a nonsuppurative panarteritis or panphlebitis and was segmental, leaving normal vessels between diseased segments. The lesions came in crops, producing complete and usually permanent obstruction, followed by the development of extensive collateral circulation. The history and physical findings were those of arterial insufficiency or superficial phlebitis. The diagnosis was based on these considerations:
1. Age. Onset was usually between twenty and forty-five years.
 2. Sex. Males predominate in a ratio of 75:1.
 3. Race. Half the patients were Jewish.
 4. Migratory phlebitis preceding or accompanying arterial disease.
 5. Severe pain at rest from ulceration or from ischemic neuritis.
 6. Absence of calcification as seen by x-ray.
 7. Small vessels of the hands might be involved. Thrombosis of mesenteric, coronary, cerebral, or renal arteries was not uncommon.
- Atherosclerosis in young men is now a well-known entity. It is a segmental disease. Thrombosis in the arteries is frequently associated with thrombosis in the veins. The arteries and veins respond to thrombosis with an inflammatory reaction, followed by various degrees of recanalization. There is reasonable doubt that thromboangiitis obliterans is a distinct clinical entity. It is certain that the diagnosis is now made much less frequently than in past years.

Thrombosis. Thrombosis of the larger arteries of the lower extremities is common in the natural course of arteriosclerosis. Whether or not dramatic symptoms of acute arterial insufficiency appear will depend on the degree of collateral circulation which has developed. Gradual narrowing of a major vessel may progress unnoticed to complete occlusion, because the symptoms of arterial insufficiency may not develop until the collateral channels begin to thrombose.

Embolus. Emboli are usually fragments from more centrally placed thrombi. The occurrence of sudden arterial insufficiency without physical findings of marked peripheral vascular disease generally indicates an embolus. The common sources are:

1. Mural thrombus from the left atrium of a patient with chronic atrial fibrillation
2. Mural thrombus from the left atrium of a patient with mitral stenosis and commonly, but not necessarily, with atrial fibrillation
3. Mural thrombus from myocardial infarction of the left ventricle or, more rarely, from acute or sub-acute myocarditis
4. Thrombi on valves from subacute or acute bacterial endocarditis

Less common sources are:

1. Thrombi in the aorta or its large branches
2. Venous thrombosis in patients with a right-left shunt from congenital heart disease
3. Venous thrombosis causing pulmonary embolization, right heart failure, and the passage of a clot through the patent foramen ovale
4. Myxoma of the left atrium

Emboli are likely to lodge at the bifurcation of large vessels. A saddle embolus riding on the bifurcation of the aorta may cause circulatory insufficiency in both lower extremities. The signs of circulatory insufficiency are usually considerably distal to the embolus because of the effectiveness of collateral circulation. The degree of circulatory impairment caused by arterial obstruction and that caused by secondary arterial spasm cannot be determined on inspection. The effects of paravertebral block must decide this question. The local examination reveals the symptoms and signs of arterial insufficiency. Loss of motion and of sensation may occur rapidly. Pain has been discussed on p. 58. At first there is no pain at the site of the embolus, but tenderness may develop after a few hours, as the embolus sets up a local inflammatory reaction in the vessel.

Exposure to Cold; Trench Foot. Extremities with normal blood vessels are injured by prolonged exposure to cold. Dependency and wetness combined with cold cause tissue damage even though actual freezing of the tissues does not occur. On warming, the injury results in extreme vasodilatation with

swelling of the part because the capillaries have been damaged. Later, true capillary flow in the skin may cease because of capillary stasis and thrombosis although flow continues through small arteriovenous communications. This gives the clinical picture of superficial gangrene in a warm part. Whether complete recovery or gangrene occurs depends upon the extent of the injury. Persistent tenderness because of fibrosis and ischemic neuritis may develop.

Obstruction of Main Arterial Trunks. Broad insertion of the scalenus anticus muscle with or without cervical rib is a rare cause of Raynaud's phenomenon or organic arterial occlusion. The vascular disturbances may be reflex from compression of a portion of the brachial plexus. At times, trauma from compression of the artery causes thrombus formation with or without embolic phenomena distal to the area of injury.

Persons who sleep with their arms hyperabducted above the head or whose occupation causes them to work with their arms hyperabducted may develop numbness and tingling from occlusion of the subclavian axillary vessels. Usually discomfort causes the arms to be moved to a different position, but gangrene of the fingers has been reported in some cases.

Syphilitic aneurysm or dissecting aneurysm may cause obstruction to the main artery supplying the limb.

Obstruction of Aorta below the Renal Vessels and Obstruction of the Vessels Arising from the Arch of the Aorta. These disorders have been considered in the preceding chapter.

Obstructive Disease of the Small Vessels. Inflammatory involvement of the smaller divisions of the vascular tree may cause local areas of gangrene. In time, thrombosis may occur in larger vessels. The cause of the arteritis is usually unknown, but occasionally it occurs as the result of a reaction to a specific agent. Occasionally, cigarette smoking is the cause and complete abstinence the cure.

SPASM OF ARTERIES AND ARTERIOLES

Raynaud's Disease and Raynaud's Phenomenon. Raynaud's disease is an idiopathic bilateral paroxysmal contraction of the arteries and arterioles of the digits, usually without local gangrene. The primary fault seems to be a local sensitivity of the digital vessels to cold. The attacks are precipitated by cold or emotion and are relieved by warming. Raynaud's phenomenon consists of paroxysmal attacks of ischemia of the digits occurring in the course of other diseases, such as scleroderma, thromboangiitis obliterans, cervical rib, arteriosclerosis, crutch paralysis, and pneumatic hammer disease.

Diagnosis of Raynaud's disease from the history

and examination is made from the following points:

1. Sex. Females are affected much more often than males.

2. Age. It is less common before puberty and after forty, although it may occur at any age.

3. Bilateral and symmetric involvement of digits. It is more common in the hands than in the feet.

4. Attacks of cyanosis can be reproduced by immersion of the hands in cold water or by cooling the body rapidly by a cool shower. The digital arteries and arterioles contract. The fingers become blue if the minute vessels remain dilated, pale if they contract. On rewarming, reactive hyperemia occurs.

5. If the disease is of many years' duration, small superficial areas of gangrene may occasionally be present.

Diagnosis of Raynaud's phenomenon is made if the above findings are noted in conjunction with organic arterial disease, scleroderma, cervical rib, or history of the use of a pneumatic hammer. In the beginning, it is frequently impossible to differentiate between benign Raynaud's disease and progressive scleroderma with Raynaud's phenomenon.

Scleroderma. This is a diffuse disease of the collagenous system with skin and visceral manifestations. The etiology is unknown. Raynaud's phenomenon is frequently seen before the characteristic skin changes occur. In many instances the skin changes are localized to the distal portions of the extremities (acroscleroderma). The skin becomes boardlike and is bound down to the underlying tissues. Decreased sweating, increased pigmentation, and calcification of the skin occur. Gangrene of the digits, with marked shortening of the phalanges, is not uncommon (sclerodactylia). Involvement of the esophagus, heart, and lungs may occur early or late in the disease (Chap. 299).

Ergotism. Spasm of the arterioles with thrombosis and gangrene is produced by ergot poisoning. In the past, it was seen in epidemic form as the result of the contamination of rye with ergot fungus (*Claviceps purpurea*). It is occasionally seen after the repeated use of ergot to induce abortion or after the use of ergotamine tartrate for pruritus.

Reflex Spasm. Any painful area in the extremities may cause symptoms and signs of ischemia from stimulation of the autonomic nervous system. The ischemia of embolus or thrombus is intensified by reflex activity. Ischemia from organic disease of the vessels, from arteriosclerosis, or from thromboangiitis obliterans may be intensified by active vasoconstriction mediated through the autonomic nerves.

Disturbances in Small Vessels from Changes in Blood

Changes in the physical state of the blood may cause small vessel obstruction. Patients with sickle-cell anemia are prone to multiple thromboses. The

leg ulcers seen in this disease are probably an example of small vessel thrombosis on the basis of mechanical obstruction caused by the sickled cells. When the titer of cold agglutinins is high, exposure to cold may cause Raynaud's phenomenon. The development of globulins which precipitate in the cold (cryoglobulins) in patients with leukemia or myeloma may also cause Raynaud's phenomenon.

PROGNOSIS IN DISEASE OF THE ARTERIES

The prognosis depends upon the age of the patient, the rate of progression of the primary disease, the degree of the development of the collateral circulation, and the amount of involvement of the cerebral coronary and visceral vessels. The clinical course is very variable. Fingers are occasionally lost, the hand almost never. One or both lower limbs are more frequently lost. The mortality and development of gangrene in embolus and thrombosis are approximately the same.

In *Raynaud's disease*, as defined in this discussion, the prognosis is good by definition. Complications are rare, and the digits are not lost. In *Raynaud's phenomenon* accompanying other disease, the prognosis is that of the primary disease. Thus, in scleroderma associated with Raynaud's phenomenon, the outlook depends on the extent and rate of progression of the scleroderma. This is true whether the sclerodermatous changes are generalized or are still localized to the extremities.

TREATMENT OF ARTERIAL INSUFFICIENCY

Chronic Arterial Insufficiency. Since the etiology of arteriosclerosis is not known, treatment directed toward prevention or removal of the primary factors is not possible. In segmental obstruction of the femoral and iliac arteries, intimal stripping and grafting offer new hope for improving the circulation.

General Care. The reduction of blood cholesterol by dietary management and by drugs has been considered in Chap. 246. Because of the frequency of diabetes in persons with vascular disease, fasting and postprandial blood sugars should be measured routinely in all such patients. Complete abstinence from tobacco should be advised.

Care of Local Areas. The care of the local area with circulatory impairment from arteriosclerosis, thromboangiitis, or damage from exposure to cold is similar. The greatest danger is gangrene in the toes. This is usually precipitated by trauma, infection, or burns, all of which can ordinarily be prevented by good foot care. Care of the feet means careful washing in tepid water at night; keeping the skin pliable with lanolin; use of a blind dusting

powder to absorb perspiration; use of warm, finely woven woolen socks in winter; careful cutting of the nails, with the ends cut straight across to avoid ingrowing nails. Epidermophytosis must be treated when present, but strong ointments or solutions are to be avoided. Soaking twice daily in 1:8,000 potassium permanganate solution is satisfactory. Dry heat is contraindicated. Remember that sensation may be impaired because of peripheral nerve involvement. Heat above the temperature of the blood raises the temperature of a part with impaired blood supply much more rapidly than that of a normal part. In this situation, the blood acts as a cooling system to lower the temperature of the tissues; if this cooling system does not function efficiently, burns occur. Heating the part by reflex vasodilatation is safe; local heat may raise the metabolism, without a corresponding increase in blood supply, and precipitate gangrene. The shoes should fit perfectly and should be broken in gradually. If any break in the skin or blister occurs from any cause, the patient should go to bed and call his physician. Reflex vasoconstriction is to be minimized. In the winter, there is need not only for adequate protection for the part itself but also for attention to preserving the warmth of the body. No local protection will keep the extremities warm if the trunk is cool and the body is attempting to preserve heat.

Reflex vasoconstriction may accompany organic occlusive vascular disease. If body warming or paravertebral block demonstrates release of reflex tone, improvement of the circulation to the extremity by sympathectomy is indicated. Some observers have reported improvement after sympathectomy even though paravertebral block caused no rise in temperature. Sympathectomy may be followed by gangrene in advanced disease because it may divert the greatly limited supply of blood from the severely ischemic tissues to the more normal tissues of the part.

Sympathectomy does not increase the flow of blood through muscles and has no direct effect on intermittent claudication. If sympathectomy is performed in patients with intermittent claudication, it should be more extensive than is necessary to release the vasoconstrictor tone of the vessels of the skin of the leg and foot. A higher sympathectomy may be effective in increasing the circulation in collateral vessels.

Buerger's exercises are useful. They have the disadvantage of being too tiresome to continue for a long period of time. They help because, when the foot is dependent, the effective arterial pressure is increased until the pressure from gravity is counteracted by an equal column of blood in the veins. The foot is emptied by raising it just far enough above heart level to produce collapse of the veins

and slight pallor. It is then returned to the dependent position. The ideal conditions are (1) maximal lowering of the foot below heart level and leaving it there until the veins are full and (2) the least elevation for the shortest period of time which will suffice to empty the foot. When the valves of the veins of the legs are competent, walking slowly is an effective form of Buerger's exercises. In many patients it appears that frequent short walks constitute the most effective of all methods of treatment. The contraction of the muscles forces blood up the deep veins, the venous pressure falls sharply as the muscles relax, and the high arterial pressure produced by gravity is effective until the veins fill.

Pyogenic infections of the feet and toes are common in patients with impaired blood supply. This is particularly true if peripheral neuritis is present. If an apparently gangrenous part is warm, infection is playing an important role, and intensive penicillin therapy may greatly change the picture. Each time the physician must ask himself: Is infection or ischemia the primary cause of the acute episode?

Acute Arterial Insufficiency. In the acute circulatory insufficiency caused by thrombosis or embolism, there are four considerations: (1) mechanical removal or bypassing of the obstruction if the occlusion is in a major vessel, (2) sympathetic blockade by paravertebral or spinal anesthesia, (3) enhancing fibrinolysis by the intravenous administration of either purified streptokinase or human fibrinolytin, followed by (4) routine anticoagulant therapy with heparin and the coumarin drugs. Operative removal of an embolus in a major vessel is usually beneficial in the first 8 to 10 hr. Thrombectomy, thromboendarterectomy, or bypass grafting is worthwhile if the occlusion is localized but is to no avail in diffuse obstructions.

Sympathetic blockade should always precede the administration of fibrinolytic and anticoagulant drugs to avoid hematomas. The type and dosage of human fibrinolytic agents are currently under investigation; they are optimal for thromboses of less than 48-hr duration.

For anticoagulant therapy, the preferred method of heparin administration is to give the initial dose intravenously and to maintain the patient thereafter on subcutaneous heparin every 4 hr. Concomitantly, one of the coumarin drugs may be administered by mouth after determining the prothrombin time; when the prothrombin level is lowered to below 30 per cent of normal, the heparin therapy is discontinued and the patient maintained on the coumarin drug exclusively. If the arterial insufficiency is the result of an embolus, effective anticoagulant therapy is usually continued for approximately three weeks until there has been time for the site of the embolus to be covered with endothelium.

Maintaining the affected part in the dependent

position may help the gravitational flow in collateral channels. Local heat is detrimental since it would increase the metabolic requirement in an area of limited arterial inflow.

Raynaud's Disease. The body should be dressed warmly so that the vessels in the hands and feet will dilate to help dispose of body heat. The hands and feet should be protected with warm socks and gloves. Minor episodes of "dead fingers" should not occasion alarm. If these measures are not adequate, Priscol given orally in doses of 25 to 75 mg every 3 or 4 hr is frequently helpful.

Raynaud's Phenomenon. Adequate heat to the body and protection of the extremities from cold and trauma are important. The response of the underlying disease to therapy is more important than the treatment of the vasospasm. When associated with scleroderma, the prognosis is guarded. Priscol has been reported to be effective in controlling the vasospasm. Sympathectomy may be tried, but the effect is usually temporary. Testosterone has been reported to have a favorable effect in scleroderma when given for several months.

Amputation. The indications for amputation are (1) gangrene, (2) uncontrollable infection, (3) intractable pain, and (4) such complete loss of function from deformity or contracture that the limb is a burden. Amputation is a last resort, and conservative therapy has saved many limbs. The site of amputation must be at a level where tissue nutrition is good. In the last analysis, the amount of bleeding at operation and the appearance of the tissues after incision determine whether the stump will be viable. Usually, clinical observation determines the level of the final incision, but special tests such as the appearance time of intravenous fluorescein and the effect of intradermal histamine may be helpful.

DISTURBANCE IN VENOUS FUNCTION

Varicose Veins. Dilatation and tortuosity of the superficial veins of the lower extremities result from constitutionally defective valves affected by postural strain or from the enlargement of the superficial circulation to compensate for obstruction of the deep circulation. The obstruction of the deep circulation usually results from deep thrombophlebitis. Increased blood flow from an acquired or congenital arteriovenous fistula is a rare cause of varicosities. The varicosities caused by defective valves are easily treated surgically. Those resulting from deep vein obstruction are compensatory, and the extremities are not helped by ligation and vein stripping.

In a normal person who stands motionless for a short time, the hydrostatic pressure in the leg veins is equal to the height of a column of blood extend-

ing from the fourth rib to the level of the vein. In a man 6 ft in height, the pressure at the ankle is about 105 mm Hg. Blood from the foot is returned by the force of the heartbeat, and all the valves are open. These pressure relations are the same, therefore, in valved and nonvalved veins. On contracting the muscles of the leg and thigh, blood is forced up the extremity by the high intramuscular tension. With normal valves, it cannot be forced downward or outward into the superficial circulation through the communicating veins. The blood in the superficial veins of the leg is not forced upward by the contraction because the skin tension does not exceed the hydrostatic pressure. When the extremity is relaxed, blood does not flow downward into the muscles because the valves control it. Blood enters the veins in the muscles from the arteries and from the superficial veins by way of the communicating veins. Backflow from the cava is prevented by valves, and the runoff through the communicating veins lowers the pressure in the superficial veins effectively. The fall in hydrostatic pressure in the venous system lowers capillary pressure effectively and prevents edema. When the valves of the veins are destroyed, the venous and capillary pressures are not lowered by exercise. Chronic edema, petechial hemorrhage, poor drainage, and infection frequently result.

Varicose veins fall into the following groups. (1) Simple dilatation of the veins with competent valves. The lowering of capillary pressure by exercise is maintained, and edema does not result. Superficial venous thrombosis in the dilated, tortuous vessels may be troublesome. (2) Varicose veins with incompetent valves in the superficial veins, but competent perforating and deep valves. On walking, the venous pressure is not lowered unless the superficial veins are prevented from filling from above by local pressure. When the superficial veins are correctly obstructed by a tourniquet, exercise effectively lowers the venous pressure. (3) Varicose veins secondary to occlusion of the deep femoral veins. The varicosities have resulted from thrombophlebitis of the deep veins, and the valves of the deep veins are destroyed. Exercise has no effect in lowering the venous pressure when walking. Brawny edema may mask the superficial varicosities, and their extent is rarely realized until the venous tree is visualized by the use of Ilypaque. Intractable chronic ulcers are common.

Treatment. The treatment of the first two groups by the combination of high ligation and injection of sclerosing solutions, or removal by vein stripping, is satisfactory. The treatment of the last group is unsatisfactory, and prevention by more intensive treatment of the deep vein thrombophlebitis is the most satisfactory answer. Once the condition is present, it is beneficial to prevent edema formation

by application of external force to counteract the effect of gravity. Bed rest with elevation of the parts allows healing. The application of pressure bandages or of a jelly boot prevents the breakdown of the healed lesion when the patient is up. One should remember the magnitude of the hydrostatic force that one must counteract when the patient stands. Ace bandages are rarely adequate; a pure rubber roller bandage 3 in. wide and 15 ft long is much more effective.

Thrombophlebitis. Thrombus formation in veins is common. Dilated, tortuous superficial varicose veins frequently become tender and hard, with redness of the overlying skin. The inflammatory reaction usually subsides uneventfully, and embolic complications are unusual. Recurrent superficial or deep venous thrombosis is a common occurrence in the natural history of obliterative arterial disease. Local trauma from the administration of various solutions and medications is a not uncommon cause of superficial thrombophlebitis. Again, embolic phenomena are rare.

Thrombus formation in veins occurs at times in all acute and chronic infections, after operations, and after childbirth. It is common in patients with chronic debilitation, heart failure, or carcinomatosis, and occasionally occurs in apparently normal persons. Venous thrombosis is apt to occur contiguous to areas of local infection or trauma. It is seen in the pelvis in puerperal infection and in the prostatic veins after prostatectomy. In the majority of instances, the thrombus begins in the deep veins of the calf and extends proximally. The process may cause very little reaction in the vein wall (phlebotrombosis), and if this is the case, the thrombus is particularly prone to break loose and lodge in the pulmonary tree. On the other hand, the reaction may involve the veins of the entire extremity, with the inflammatory reactions extending into surrounding lymph channels (thrombophlebitis). With an extensive reaction, the clot adheres tightly to the vein wall, and then embolic phenomena are less common.

The precise etiology of thrombophlebitis is unknown. Slowing of the blood stream seems to be an important factor in thrombus formation. Acceleration of the clotting time probably plays a part. The role of changes in the vein walls has not been determined. In spite of the severe systemic reaction and the evidence of the reaction of inflammation in the extremity in the more fulminating cases, no infectious agent has been found.

Local symptoms may be absent. A rise in pulse rate or an unexplained slight fever in a patient in bed may be the only sign of phlebotrombosis, and the condition may not be recognized until an embolus has lodged in the pulmonary artery. Several days later, tenderness in one or both calves

may occur. Tenderness in the calf and pain in the calf on dorsiflexion of the foot may be the only sign. If the foot is dependent, slight edema and cyanosis may be observed. Other findings may include a measurable, although not always visible, increase in the circumference of the calf as compared to the opposite leg, slight prominence of the veins, increased local warmth or diminished pulsation on the affected side, and local pain on compression with a blood pressure cuff at a pressure of 80 to 120 mm Hg.

At the other extreme is the painful, swollen, cyanotic leg of acute thrombophlebitis. In this condition, the arteries are not involved directly; intense reflex vasoconstriction may occur, however, and at times the arterial pulse is felt with difficulty. Fever and leukocytosis are present.

Treatment. The treatment is divided into three parts:

1. Prevention of clot formation in the leg veins by early ambulation or by bandaging of lower extremities when the patient is confined to bed, and by the use of heparin and bishydroxycoumarin (Dicumarol).

2. Prevention of pulmonary emboli after leg veins are involved. Anticoagulant therapy is usually successful. Pulmonary emboli continue in an occasional patient, and ligation of both common femoral veins or the vena cava becomes necessary. (Embolism and infarction of the lungs are discussed in Chap. 262.)

3. Prevention of destruction of lymphatic vessels and veins which leads to persistent edema and chronic ulcers. Pain is relieved and edema clears more quickly when the sympathetic tone is released by repeated paravertebral blocks. Anticoagulant therapy may reduce the number of vessels permanently thrombosed. Elevation and proper bandaging will minimize the edema. Particular attention to bandaging should be given when the patient is allowed to be up.

DISORDERS OF PERIPHERAL LYMPHATIC VESSELS

Water and electrolytes which leave the capillaries can reenter the capillaries without difficulty. Protein and various forms of particulate matter pass into the lymphatic capillaries. If the lymphatic drainage to a part is blocked, the extracellular fluid will gradually assume a high protein content. The capillary filtrate may contain very small amounts of protein, but as the water can be reabsorbed by the blood capillaries and the protein cannot, an effective concentrating mechanism is present. When the lymph vessels are normal, lymph flow depends on muscular contraction, respiratory movements, transmitted movements from arterial pulsations, and to

a certain extent, on gravity. Complete immobilization of the lower extremity in a patient sitting in a chair leads to physiologic lymphatic obstruction.

Acute Lymphangitis. When bacterial infection in an extremity is not localized, the inflammatory products pass proximally along the lymphatic channels. The material carried in the lymph channels causes dilatation of the small blood vessels about the lymph vessels, and their courses are outlined by one or more red streaks. Before chemotherapy was available, lymphangitis always carried a serious prognosis because it is a sign of uncontrolled, spreading infection. Immobilization of the part greatly reduces the rate of spread of the infection by reducing the rate of lymph flow. With chemotherapy, fear of lymphangitis and the surgery necessary with lymphangitis has largely disappeared.

Chronic Lymphatic Obstruction. Widespread obstruction of the lymph vessels may result from congenital or familial disorders of the lymph vessels. The lymphedema of the familial type is called Milroy's disease. Acquired chronic lymphedema results from obstruction of the lymph channels by neoplasms, scar, operative removal of lymph nodes, and fibrosis caused by x-ray therapy. It may follow low-grade lymphangitis from filariasis, from lymphogranuloma venereum, and from repeated streptococcal infections. It may be a complicating factor in certain instances of severe edema following thrombophlebitis.

In its early stages, lymphedema cannot be distinguished physically from any other form of soft pitting edema. On laboratory examination, the high protein concentration separates it from cardiac and nephritic edema but not from the fluid of myxedema. Lymphedema causes fibrosis in the tissues, and in time the tissue becomes hard and brawny. The skin may be thick and folded with indolent ulcerations.

Treatment of Chronic Lymphedema. Early and persistent therapy is important. If marked edema is prevented by postural drainage, by effective bandaging, and by limiting upright activity to periods short of edema formation, much of the fibrosis and recurrent infection will be prevented. This program calls for persistence on the part of both physician and patient. Acute attacks of lymphangitis can be controlled by appropriate chemotherapy.

LEG ULCERS IN PATIENTS WITHOUT PERIPHERAL VASCULAR DISEASE

In a normal person, an injury to the skin of the foot or ankle is much more serious than one to the hand or wrist. In the ambulatory patient, lesions on the lower leg and foot may heal slowly. If healing does not occur promptly, the patient should be put

to bed and the part elevated. If the lesion is allowed to become chronic, low-grade local phlebitis, lymphangitis, and arteritis develop. Even if the main vessels to the part are unaffected, these local changes cause poor tissue drainage and there is a tendency to recurrent infection and ulceration. A nonhealing, nontraumatic ulcer of the lower leg is an emergency and requires bed rest until healing occurs.

SPECIAL DIAGNOSTIC TESTS

The history and physical examination will establish the presence or absence of arterial insufficiency. When the circulation is normal, no instruments are necessary to demonstrate the fact. The skin shows no trophic changes and does not blanch abnormally on elevation. The arterial pulses are palpable. If the main artery is occluded by pressure for several minutes, release of pressure will cause bright-red reactive hyperemia. Heating of the body causes the extremities to warm, and immersion of the part in hot water brings out the capillary pulse. Histamine pricked into the skin produces a typical wheal and erythema. When there is obvious arterial insufficiency, these findings are changed as outlined under Special Points in History and Physical Examination. When other signs of arterial insufficiency are present, it is not safe to attempt to demonstrate the capillary pulse by placing the involved extremity in hot water.

Special tests have been of value in understanding the normal physiology of the peripheral circulation. They have been of use in quantitating the degree of damage caused by pathologic processes and have aided our understanding of the development of collateral circulation. They have been useful in determining, in at least a semiquantitative way, the effects of therapy in occlusive vascular disease.

The following tests are useful at times:

1. Measurement of skin temperatures in a cool room (18 to 20°C) before and after release of sympathetic tone. When the blood supply is decreased by occlusive arterial disease or by reflex vasoconstriction, or by both, the extremities cool. Release of sympathetic tone is accomplished by paravertebral block, by spinal anesthesia, or by raising the rectal temperature by body warming. If the skin temperature does not rise, the decrease in blood flow is the result of occlusive vascular disease. A rapid rise to 30.5 to 33°C indicates normal blood supply. An intermediate rise indicates both reflex sympathetic constriction and occlusive vascular disease. This test has the virtue of simplicity and has proved to be of clinical use.

2. Arteriography and venography. The arterial tree is visualized by x-ray after the intraarterial in-

jection of 50 per cent Hypaque or other contrast media. When the femoral pulses are absent, injection is made into the aorta. The exact point of arterial obstruction and the pattern of the collateral circulation can be determined. It is helpful in showing segmental occlusion in the iliac and femoral vessels. These lesions can now be approached surgically. Visualization of the veins by the injection of Hypaque is occasionally useful.

3. Circulation time to the extremities. Several methods are available. The fluorescein test is the most objective. For this, 3 ml of a 20 per cent aqueous solution of fluorescein is injected quickly into the antecubital vein, and the time of appearance of a greenish-yellow glow in various parts of the body is observed. When arterial insufficiency is present, the appearance time of the fluorescein is prolonged. In severe ischemia no fluorescein may appear.

4. Oscillometer. This is a volume recorder which magnifies the changes in volume which normally occur with each cardiac systole. The ordinary blood pressure recording apparatus may be used as a crude oscillometer. Refinements of the oscillometer have not increased its clinical usefulness.

5. Histamine wheal test. If the arterial circulation is inadequate, histamine pricked into the skin gives a subnormal or absent reaction.

6. Measurement of blood flow by plethysmographic techniques has advanced our knowledge of the circulation, but the method is not suitable for routine clinical use.

B. DISEASES OF THE HEART

INTRODUCTION

William H. Resnik and
T. R. Harrison

In previous chapters the basic mechanisms underlying the important manifestations of disorders of the heart have been described. In the succeeding chapters, the clinical aspects of heart disease are presented.

"Curable" Heart Disease. The term "curable" requires definition. The patient whose heart disease stems solely from a patent ductus that has been closed may be considered cured in the strictest sense. The patient with valvular heart disease whose intractable heart failure has been eliminated by the adequate treatment of an associated thyrotoxicosis is not "cured" in the sense that the heart has been restored to structural normality. Nevertheless, he has been cured of heart failure in that it may now be possible for him to lead a practically unrestricted life. In other words, we mean by curable a form of heart disease that is amenable to specific treatment,

even though an anatomic lesion may continue to exist.

The introduction of the important differentiation between low-output and high-output failure (p. 99) not only has clarified veering and disputed points of view regarding the nature of heart failure, but it has brought into focus a group of disorders with high-output failure that are susceptible to cure. In addition, the spectacular advances in cardiac surgery and the development of potent antibiotics have completely altered the previous hopeless outlook of persons afflicted with many forms of congenital and acquired heart disease. As a consequence, we can no longer be content with the mere recognition that heart disease exists. We must be constantly mindful that the patient may have a curable form of heart disease. Overlooking such a disorder constitutes a far graver error than diagnosing incorrectly a form of heart disease that could not have been better treated even if it had been precisely recognized. The restoration of a patient to a normal life of useful activity by the discovery and appropriate treatment of bacterial en-

docarditis constitutes a far greater triumph than the lucky speculation at the clinical pathologic conference that the patient with the typical history of ischemic pain has suffered from endocardial fibroelastosis and not from coronary obstruction.

Moreover, the proper management of heart disease and of heart failure is based on something more than recognizing a "cause," e.g., rheumatic heart disease with mitral stenosis, and administering the standard procedures for the control of congestive failure. In all cases, *every possible contributing factor should be considered and treated if present*: infection and emotional stress, excessive activity and ingestion of salt, anemia, hyperthyroidism, thiamine deficiency, electrolyte imbalance, etc.

Cardiac Reserve. Cardiac reserve is the capacity of the heart to respond to increasing burdens without displaying manifestations of failure. In practice, the reserve is ordinarily estimated by observing the patient's response to varying degrees of activity. When more accurate information is required, hemodynamic measurements before and after exercise or after the administration of digitalis are necessary. In a previous chapter (p. 93) the question of cardiac reserve and the physiologic problems associated with it have been discussed in detail. Suffice it to repeat here that any increased work that is imposed on the heart, whether by augmenting its output, or the pressure that it must eject against, or its rate of beating, diminishes the cardiac reserve; and the loss of cardiac reserve is proportional to the increased energy requirements demanded by the added load. Experimental observations demonstrate that, for a given increase of work, increased volume (cardiac output) is least costly in terms of cardiac reserve, whereas increased heart rate is most costly and hence most destructive of cardiac reserve.

These experimental observations conform with clinical experience. *The failing myocardium is always overloaded in relation to its contractile strength. Anything that is responsible for a rapid heart rate constitutes a deleterious influence on an already overloaded heart, and this explains why, for example, ectopic tachycardias are so harmful in myocardial infarction.* The experimental observations explain why patent interventricular septum is usually so much more serious than patent interatrial septum, since in the latter lesion the primary load is a volume load, the least serious, whereas in the former there is in addition to the volume load a further pressure load, far more serious. Aside from the administration of digitalis which increases the efficiency of the myocardium, everything that the physician utilizes is designed to diminish the load of the already overburdened heart.

The Senile Heart (Presbycardia, the Aging Heart). Clinicians have long been familiar with the progressive loss of cardiac reserve with advancing years. The most thoughtful and lucid expression of the concept was given by William Dock. We consider its appreciation essential in understanding many otherwise perplexing problems of heart disease. The reserve capacity of the youthful heart is very great, and it is a matter of common experience that *the young person will tolerate without difficulty a burden such as a severe thyrotoxicosis or a paroxysmal tachycardia of long duration whereas an older person will develop congestive failure with the same disorders*, even when of milder intensity and briefer duration. The explanation for the effect of age on the adaptive capacity has never been clearly understood, chiefly because no histologic lesion in the aging myocardial fibers is visible that could account for the loss of efficiency. One widely accepted view has held that the diminished cardiac reserve in the aging individual is caused by an *ischemia that increases with age*, either because of the development of diffuse arteriolar disease in the coronary bed or because of the inadequate growth of capillaries to the myocardial fibers. Dock's perfusion studies have clearly indicated that ischemia is not the basis of myocardial failure in the aged, when there is no gross atheromatous involvement of the epicardial portions of the coronary arteries. Since the biochemical defect is as yet unknown, Dock ascribes the loss of cardiac reserve to normal aging or involutionary processes. The extent to which involution impairs myocardial efficiency varies from individual to individual at the same age, just as physical fitness and mental alertness are differently affected in aging persons. This explains why one person may tolerate a very high arterial pressure, for example, whereas another person of the same age suffers from congestive failure caused by an elevated pressure of much more moderate degree, when meticulous clinical as well as autopsy studies reveal no reason for the difference.

There can hardly be any dispute about the influence of presbycardia on the heart that has already sustained an impairment of cardiac reserve. The valvular lesion that caused no symptoms whatsoever at twenty may lead to severe disability at fifty, or the hypervolemia due to a saline infusion which is easily tolerated by the young adult may precipitate congestive failure in the elderly subject. There has been far more skepticism about the ability of age alone, pure presbycardia without any additional load, to cause failure of the myocardium. One is necessarily uncertain about the relative contributions of involution and coronary sclerosis to the development of failure in the aged, especially when the atheromatosis of the coronaries is of very

moderate degree and has given rise to no clinical or anatomic manifestations of ischemia. But *there are occasional instances of heart failure in the elderly, carefully observed during life and at autopsy, when coronary disease, hypertension, valvular disease, anemia, thyrotoxicosis, etc., have been excluded and histologic examination reveals no structural myocardial disease. We believe that these represent myocardial failure caused by senile heart disease alone.* We do not mean to imply that the diagnosis "senile heart disease" should become a scrap basket for all forms of heart failure in individuals over the age of forty-five or fifty, although the scrap-basket diagnosis of "arteriosclerotic heart disease," for which there is little or no evidence when there is no gross atheromatous disease of the coronaries, seems to be accepted without protest by those who demur at the diagnosis "presbycardia or senile heart disease."

It would be preferable if we conceded frankly that the diagnosis should be: "heart disease and failure of undetermined origin"; that some degree of coronary disease will probably be found in a high percentage of cases, although the relationship of the coronary disease to the failure may be in doubt when there is no clear evidence that it has led to a critical diminution of coronary flow; but in a small percentage of cases, no physiologic or biochemical or anatomic cause for the failure will be demonstrated. The frequency with which this latter occurs is a matter of dispute; certainly, it is not common. Nevertheless, we do not believe that the concept of the aging myocardium, presbycardia, can be in doubt.

The Scope of "Heart Failure." Some believe that this term should be applied only to myocardial failure and should even be still further limited to failure of the ventricular myocardium. This concept holds that the congestive syndromes resulting from stenosis of the atrioventricular valves or from pericardial disease are not heart failure. In our opinion "heart failure" should include all disorders in which congestive phenomena occur as the result of the inability of the heart to receive and propel the blood which is offered to it. The principle involved is the same whether heart failure is due to aortic stenosis or to mitral stenosis, even though in the one case it is inadequacy of the thick left ventricle and in the other incompetence of the thin atrium. In these instances and in patients with endocardial fibrosis or with constrictive pericarditis, congestive phenomena due to structural disease of the heart are observed and the restriction of the term "heart failure" to those disorders in which the ventricular myocardium is at fault can lead only to confusion.

(The concept that heart failure occurs when cardiac output is inadequate in relation to filling load

(p. 100) is also of importance in comprehending the significance of the high-output disorders which, as already mentioned, are likely to be curable. In the case of most of these, such as thyrotoxicosis and anemia, the presence of congestive phenomena indicates heart failure. However, when there is a primary increase in blood volume (as contrasted to hypervolemia secondary to heart failure), such as may occur in the oliguric states induced by acute renal necrosis or by glomerulonephritis or following administration of intravenous fluid in excessive quantities to elderly patients, a true state of "noncardiac circulatory congestion" may exist. Under such circumstances, slight elevations of venous pressure and even of ventricular end-diastolic pressure may be present without heart failure. Since in the case of the young normal heart the output may increase severalfold without significant rise in pulmonary pressures, it is not likely that pulmonary capillary pressure can increase so much as to exceed oncotic pressure as the result of hypervolemia alone. The degree of hypervolemia and hence of filling load required to produce such a marked elevation of the pulmonary pressure will necessarily depend on the myocardial reserve. This explains why the state of "noncardiac circulatory congestion," induced by intravenous fluids, rarely leads to true heart failure in young persons but frequently does so in elderly subjects with previously asymptomatic presbycardia. In any patient with an elevated filling load, the presence of rales constitutes strong evidence that true heart failure is present. The differentiation between the rare disorder "noncardiac circulatory congestion" and heart failure thus depends largely on the presence of rales, gallop, and especially on the demonstration that digitalis administration produces improvement.

The Total Picture. The physician should constantly bear in mind that a single laboratory or instrumental report should rarely be the sole basis on which a clinical judgment is based. If we emphasize the electrocardiogram in the following chapters, it is only because this particular form of evidence pertaining to the heart is so widely employed and one to which so much deference is paid. The clinician should never forget that the electrocardiogram is a very precise instrument but the information that it affords us is limited. Technical errors may lead to confusion. The person who interprets the tracings is not infallible, and the most experienced and authoritative electrocardiographers may disagree about the reading of a record. The physician would do well to be wary about being misled by a purposefully and even necessarily ambiguous report: "consistent with myocardial ischemia." Practically any type of tracing is consistent with myocardial ischemia, even a perfectly normal record,

let alone one displaying minor S-T or T-wave alterations. We do not mean to imply that the electrocardiogram is to be ignored. We do mean to emphasize that the physician must not relinquish his responsibility, which is to integrate the total picture: history, physical examination, as well as data obtained by instrumental and laboratory procedures. He should not permit his judgment to become paralyzed by a report dictated in a distant office by a person who has available only a fraction of the information necessary for a valid decision about the condition of a patient. Above all, he should avoid the fallacy of treating the electrocardiogram and of creating an iatrogenic invalid. Negative T waves do not constitute a disease. Exactly the same admonitions apply to murmurs, irregularities of the heart, and other deviations from the norm. Each must be interpreted in the context of the total picture. *The clinician must remain a clinician and not become a mere recipient and slave of reports; that is, he must never cease exercising judgment in his management of a clinical problem.* Finally, in his assessment of the total picture, he must constantly bear in mind that even the person with unquestionable organic heart disease may be suffering from symptoms of psychogenic origin and that these may be responsible for more concern and apprehension than may be caused by structural disease.

249 CONGESTIVE HEART FAILURE

T. R. Harrison and
 William H. Resnik

The patient with cardiac disease may face any one of four major hazards or a combination of them. These are (1) inadequate coronary circulation, (2) bacterial endocarditis, (3) embolic complications, and (4) congestive failure. The first three of these

hazards are dealt with in Chaps. 254, 151, and 262, respectively, and the present chapter is limited to the subject of congestive failure. This may be defined as that disorder in which the response of the heart is inadequate in relation to the blood which is offered to it (p. 100).

NATURAL HISTORY

The concept of the senile heart (Dock's presbycardia) is fundamental for the understanding of the pathogenesis of many instances of heart failure. It explains why loads which are readily tolerated by young persons may lead to severe and even fatal failure in elderly individuals (p. 1378).

Heart Failure with Effort. Manifestations and Diagnosis. The early symptoms of heart failure are undue dyspnea and fatigue during muscular exercise. Since ready fatigability occurs in so many diseases it has little diagnostic import, and when due to cardiac disease it is often masked by the discomfort of breathlessness. Thus the recognition of incipient heart failure depends, in the main, on the evaluation of dyspnea.

The patient's age, weight in relation to height, and exercise habits must be evaluated before it is decided that the shortness of breath is anything other than a normal physiologic phenomenon. Likewise, the emotional status must be considered. Worry about the presence of a minor valve lesion may lead to a sensation of smothering, with the typical sighing which is so characteristic of the anxiety state (p. 391).

Even when an individual's shortness of breath is known to be beyond the physiologic limits, it does not necessarily follow that cardiac disease is the cause. Frequently, emphysema, advanced bronchitis, or other pulmonary disorders are responsible. Less commonly, anemia or even muscular weakness consequent to any grave constitutional disorder may lead to some shortness of breath. The differential diagnosis of dyspnea has been discussed in some detail in Chap. 14, but three points merit emphasis here: (1) In deciding whether dyspnea is of cardiac origin, the presence of clinical, electrocardiographic, or radiologic evidence of organic cardiac disease is important but not necessarily conclusive. (2) The measurement of circulation time is a simple and valuable procedure. With the exception of those disorders associated with increased cardiac output (Chap. 13), cardiac dyspnea of significant degree is associated with prolongation of the circulation time through the lungs. On the contrary, noncardiac dyspnea is usually associated with normal values. (3) In most borderline situations the response to a therapeutic test will supply conclusive information. If the dyspnea is of cardiac origin, the administration of digitalis

and of a mercurial diuretic, plus the ingestion of a salt-poor diet, will usually produce decisive benefit within 3 or 4 days. The patient's subjective impression concerning his dyspnea should be supplemented by observation of the breathing after a given exercise and, in doubtful instances, by measurements of circulation time before and after the therapeutic test.

Heart Failure at Rest. Manifestations and Diagnosis. After a period of months or years, the patient with cardiac dyspnea tends to progress into a state of frank congestive heart failure (advanced heart failure). At this time symptoms begin to be present at rest. In some instances these symptoms are related to congestion of the lungs alone, and there is no evidence of systemic congestion. The patient then has shortness of breath in the recumbent posture and frequently suffers from paroxysms of dyspnea (see discussion below, under Acute Failure of the Left Side of the Heart). The evidences of cardiac enlargement are likely to be clearly apparent, and gallop rhythm is the rule. Rales at the lung bases will usually be found, but their absence does not exclude the presence of left-sided heart failure associated with congestion but without edema of the lungs. Some patients display hydrothorax at this time, but in most instances this complication occurs later as general anasarca begins to appear.

The clinical picture of left-sided failure is usually so distinctive as to offer little problem in diagnosis. In doubtful instances, measurement of the circulation time and observation of the response to digitals will usually remove all doubt.

Eventually, the pattern of right-sided heart failure develops. In some instances this does not appear until the patient has already experienced the phenomena of left-sided failure for some weeks or months. However, occasionally the two sides of the heart appear to fail at about the same time. The usual signs of right-sided failure are distention of the veins associated with increased venous pressure, the presence of an enlarged, tender, and often painful liver, edema, albuminuria, and frequently cyanosis. Hydrothorax is usually present when there is failure of both sides of the heart, and is of great practical importance because of the relief that frequently follows removal of fluid. The right pleural cavity is affected somewhat more frequently than the left. This is possibly related to the tendency of some patients with heart failure to lie on the right side more than on the left.

Ascites is present in almost all instances of advanced right-sided failure and, under certain circumstances, may be out of proportion to the fluid accumulation elsewhere. This is seen frequently in children, in patients with constrictive pericarditis, and in patients with rheumatic disease affecting the tricuspid valve. Patients with mitral stenosis

may also exhibit prominent ascites with only slight edema of the legs. This is probably to be ascribed to anatomic changes in the pulmonary arterial branches, with secondary mechanical limitation of congestion and edema of the lungs. Thus orthopnea is minimal, and the effect of gravity on the distribution of dropsical fluid is less pronounced than in most instances of congestive failure.

The clinical picture of a patient with right-sided failure or with combined failure of the left and right sides of the heart is so characteristic that ordinarily there will be no difficulty in recognizing it. Other disorders such as cirrhosis of the liver and thrombosis of the hepatic veins (Chiari's syndrome), which may produce enlargement of the liver and ascites, are not associated with elevation of venous pressure in the arms unless congestive failure is also present. Obstruction of the superior cava may lead to striking distention of the veins of the neck and chest, with edema of the upper part of the body. However, the evidences of collateral circulation are usually outspoken. Edema due to renal disease, to hepatic disorders, or to rarer causes can usually be readily differentiated from the edema due to heart failure, by the absence of venous distention, of rales in the lung bases, of orthopnea, etc.

In a few patients the pain consequent to hepatic congestion may lead to confusion with primary intra-abdominal disorders. This error can be avoided by a thorough examination of the circulatory system as well as of the abdomen.

Many patients without cardiac failure display prominence of the cervical veins when recumbent. Distention of these veins is indicative of increased venous pressure only when it is present in the sitting or semisitting position. In doubtful instances the demonstration that compression of the upper abdomen causes marked distention of the cervical veins may be helpful. Patients who are recovering from cardiac failure may not have elevation of venous pressure. Likewise, individuals in whom heart failure develops very suddenly, without sufficient time for compensatory elevation of blood volume, may have no measurable increase of venous pressure despite marked edema of the lungs. In other patients with rapidly developing failure there may be distention of the central and cervical veins, with collapse (or constriction) of the peripheral veins. As a rule, however, this function is elevated in individuals with failure of the right side of the heart.

The distinction of heart failure from hypervolemic states and the relationship of "noncardiac circulatory congestion" to heart failure have been discussed on p. 1379.

Progression of Heart Failure. The advance from the early stage, with dyspnea only on effort, to the full-blown picture of combined left- and right-sided

failure may occur gradually over a period of years, even though there is no evidence of increasing load. In such an instance, either progressive myocardial disease or loss of myocardial reserve as the result of the aging process is probably responsible. More commonly, however, progression tends to occur in a jerky, stepwise fashion rather than in a slow continuous evolution. Anything which accelerates the heart rate or increases cardiac output is likely to precipitate the next stage of heart failure. Thus any ectopic tachycardia may precipitate grave heart failure in a person with diminished cardiac reserve due to disease or age. Also important are other causes of tachycardia, such as fever from any cause, respiratory infections with severe coughing, excessive physical exertion, prolonged and severe emotional stress, anemia consequent to concurrent disease in other areas, pregnancy, and especially, pulmonary infarction. Another frequent aggravating cause of heart failure is the excessive ingestion of salt.

COMMON CLINICAL FINDINGS

There are a number of situations in which the heart fails suddenly. They include myocardial infarction, fulminant myocarditis, certain ectopic tachycardias, and various rarer disorders. These several types of acute cardiac failure are associated with evidence of minimal systemic congestion, because they set in so rapidly that there is not time for compensatory increase in blood volume to occur. Hence these conditions are likely to be characterized by a shift of blood from one portion of the circulation to another, and in most instances, the clinical picture mimics that of peripheral circulatory failure or shock, the manifestations of congestion being limited to the pulmonary vascular bed. This type of sudden cardiac failure is discussed in Chap. 13 and need not be considered further here. However, there is one form of acute heart failure which merits detailed discussion because of its frequency and of its response to therapy. This is the condition known as *cardiac asthma* or *acute pulmonary edema*.

Acute Failure of the Left Side of the Heart (Paroxysmal Dyspnea, Cardiac Asthma, and Acute Pulmonary Edema). Patients with hypertension, with lesions of the aortic valve, and with coronary sclerosis frequently are awakened by seizures of dyspnea. Similar attacks may occur in patients with mitral stenosis when marked tachycardia, due to exercise or an ectopic rhythm, reduces the diastolic filling period. Various names have been applied to these episodes. The severe and fatal instances are characterized by acute edema of the lungs. In many of the patients the moist rales are limited to the bases, and the physical signs are chiefly those of

bronchial obstruction, with wheezes and rhonchi. It is probable that edema of the bronchial walls is especially important here, although some believe bronchospasm to be concerned. When the number of moist rales is limited in relation to the wheezes and squeaks, the condition may be confused with bronchial asthma or with other causes of wheezing. Since the episodes usually occur at night, the term *paroxysmal nocturnal dyspnea* has been widely employed, but it has the disadvantage that similar episodes may occur during the day and that other diseases, such as bronchial asthma, occasionally cause paroxysmal dyspnea at night. From the standpoint of tradition there is some advantage in retaining these several terms, provided it is clearly understood that they all refer to one fundamental disorder—acute failure of the left side of the heart.

Acute left ventricular failure may be induced either by abrupt decrease in strength or by sudden increase in load. In the former instance, which is usually the result of acute myocardial infarction, there is no time for compensatory increase in total blood volume to occur and the combination of sudden trapping of blood in the pulmonary circuit with decline in cardiac output produces decrease in blood pressure and the picture of oligemic shock in the systemic vessels.

More commonly, these seizures are precipitated by an elevated filling load. This is usually caused by a temporary increase in total blood volume consequent to the recumbent posture, with reabsorption of extracellular fluid from the dependent parts of the body. Under these circumstances there is no deficiency of blood in the systemic area, the cardiac output and blood pressure are well sustained, and the shocklike state is minimal or absent. Less important causes of increased venous return and filling load are cough, nightmares, excessive warmth, and possibly abdominal distention. Ordinarily, they represent the final straws which may awaken the patient or exaggerate the effects of the reabsorbed fluid.

In a typical instance the patient, who has previously had some shortness of breath on effort but no symptoms at rest, retires for sleep in his usual state of health. After an hour or more he is awakened with a sense of suffocation, sits up, and may seek an open window. At the same time there is some coughing, and examination of the lungs at this period will reveal a few moist rales at the bases and scattered squeaks over the lung fields. In most instances the attack subsides after a few minutes of panting and coughing in the upright position. However, in the more severe attacks the dyspnea becomes progressively worse, the cough more severe, and there is expectoration of copious frothy sputum tinged with blood. Examination reveals scattered wheezes and squeaks and, in addition,

moist rales all over both lung fields. This is acute pulmonary edema, which may be fatal within an hour or two unless appropriate therapy is promptly instituted.

The gravity of the attacks is related to the degree of transudation from the pulmonary capillaries. This depends on the balance between the oncotic and mechanical pressures. Because of the low pressure (8 to 10 mm Hg) normally present in the pulmonary capillary bed, there is a wide margin of safety. Increments up to a value of about 25 mm Hg lead to congestion of the lungs and relatively mild dyspnea. At higher levels the oncotic pressure is exceeded and the rapidly developing pulmonary edema causes the more severe attacks.

Typically, these seizures occur in patients with left ventricular failure due to hypertension, lesions of the aortic valve, or myocardial disease. The first episode may be initiated by a myocardial infarction, which may be painless.

Attacks of dyspnea which awaken the patient from sleep are rather uncommon in patients with mitral stenosis, except when precipitated by atrial fibrillation or pulmonary infarction. However, persons with mitral stenosis may suffer from acute pulmonary edema precipitated by exertion or even by recumbency. In the latter instances the attacks usually begin before the onset of sleep.

Diagnosis. Disorders other than left-sided heart failure may cause acute pulmonary edema. It may occur in patients with inspiratory obstruction or be caused by inhalation of irritating gases or particulate matter.

Acute pulmonary edema may develop following severe brain injury, e.g., in massive intracerebral or intraventricular hemorrhage or in bulbar poliomyelitis. Although acute hypertension may be present, the precise mechanism is disputed and little can be done to alleviate the situation.

Gravely ill, comatose patients often exhibit coarse and rattling respiration. This does not represent true pulmonary edema but instead is due to accumulation of mucus in the bronchi because of muscular weakness and depression of cough reflexes.

Treatment. The initial step should be the administration of morphine or an allied drug. The benefit resulting from respiratory depressants is probably due to the effect of these drugs in breaking the vicious cycle whereby dyspnea, itself a result of congestion of the lungs, leads to reduction of mean intrathoracic pressure, which causes greater inflow into the right ventricle and increase in the severity of the congestion when the left ventricle is less able to propel the blood offered to it. Thus dyspnea causes more congestion, which causes more dyspnea, and so the vicious cycle proceeds until the respiration is depressed by a drug of the morphine group.

Reduction of venous return to the right side of the heart can be accomplished to some extent by *venostasis*, which consists in applying tourniquets to three extremities. Every few minutes a tourniquet is placed on the fourth extremity and one of the others is released. Thus the danger of thrombosis is minimized. In the severer instances venesection should be employed, and one should not hesitate to withdraw as much as a liter of blood in successive bleedings of 500, 300, and 200 ml.

Oxygen is urgently needed in patients with acute pulmonary edema. Details concerning its administration are presented in Chap. 268.

When patients who have not received digitalis develop acute pulmonary edema, the rapid-acting digitalis preparations must be administered immediately. Lanatoside C (Cedilanid) should be given intravenously. The total dose for a patient not previously receiving digitalis is usually 1.2 to 2.0 mg, which may be given over a period of 2 hr, or less, in urgent instances. The initial dose should be 0.8 mg, and subsequent doses of 0.4 mg may be given at half-hourly intervals.

When a patient has already been receiving digitalis the problem is more difficult. Once it has been determined that the patient is only partially digitalized, then lanatoside C should be used with caution in an initial dose of 0.4 mg, followed by 0.2 mg at half-hourly intervals, until improvement occurs or evidence of digitalis intoxication appears.

In the *prevention* of attacks of acute pulmonary edema the following principles of therapy are important: (1) The maintenance of adequate digitalization. (2) The treatment of extracellular fluid excess, even though there may be no detectable pitting edema. This involves the utilization of diuretics and restriction of sodium chloride. (3) Every attempt should be made to avoid the precipitating factors. A patient who has been having attacks of acute pulmonary edema should sleep in the semi-sitting position and should have a special bed when this is available. Mild sedatives should be administered to minimize disturbing dreams. Cough and emotional stresses should be controlled so far as possible. The evening meal should be small, in order to minimize cardiac work. When the condition occurs repeatedly, a responsible member of the family should be instructed in the administration of morphine or an allied drug as soon as the attack begins. Otherwise, the patient may succumb before the physician can reach the bedside.

To summarize, attacks of pulmonary edema can be best prevented by vigilant and vigorous application of those therapeutic principles which are used to treat heart failure in general, and which are discussed later in more detail.

Periodic Breathing. In elderly persons with failure of the left side of the heart, periodic breathing

(Cheyne-Stokes respiration) may be accompanied by recurrent brief episodes of dyspnea. The same patient may have this periodic dyspnea as he dozes off to sleep and then be awakened by acute pulmonary edema. More commonly, a patient has only one of these syndromes. The treatment of nocturnal dyspnea due to Cheyne-Stokes respiration is essentially that of heart failure in general. However, opiates should be used sparingly, and the milder sedatives are often efficacious. This type of dyspnea usually indicates a poor prognosis but, unlike acute pulmonary edema, does not constitute a grave emergency.

Chronic Congestive Heart Failure. The majority of patients who have chronic heart failure have involvement of both sides of the heart. All the manifestations of both right- and left-sided failure are present in many patients, but some of them present only a portion of these manifestations, such as edema without detectable hepatic enlargement, or the reverse situation. Other patients will have right-sided hydrothorax with no other evidences of failure of the right ventricle. In such instances it is uncertain whether the accumulation of fluid in the pleural cavity comes from the visceral pleura and is a manifestation of left-sided weakness, or whether it arises from the parietal pleura and is the result of early right-sided failure. The rarity of hydrothorax in patients with involvement of one side of the heart only and its frequency when left and right failure coexist suggest that congestion of both parietal and visceral pleura may be necessary for its development.

It should be emphasized that slight pitting of the ankles at the end of the day occurs in many healthy persons. Individuals who have lost weight frequently have a palpable liver. Elderly persons who are leading a sedentary life are often short of breath on exertion. Emotional disturbances may rarely cause episodes of shortness of breath (usually described as "smothering") at night. Thus there may be some doubt in a borderline situation as to whether a patient does or does not have cardiac failure. In such an instance observation of the response to a diuretic and to digitalization will usually supply conclusive evidence. When the symptoms mentioned are not due to cardiac disease, little or no improvement will be noted, and even this will be mainly the result of suggestion. When, however, such apparently minor symptoms are in reality the earliest indication of myocardial failure, the administration of digitalis to a patient who has not previously received it, and of diuretics, will usually result in such striking improvement as to remove all doubt from the physician's mind. Actually, in most instances such a therapeutic test is not necessary because the presence of a diastolic gallop will often settle the question conclusively.

However, one should remember that the presence of objective evidence of cardiac disease, such as an organic murmur or an unquestionable abnormality of the electrocardiogram, does not necessarily mean that the symptoms are the result of cardiac disease. Individuals with such minor cardiac abnormalities may have symptoms which are the result of coexistent emotional or physical disorders. In such persons impressive responses to digitalis and diuretics will not be observed.

It should be emphasized again that the diagnosis of congestive failure must not be based on any one manifestation but rather on a combination of them. Thus enlargement of the liver and ascites may be the result of cirrhosis, and an almost identical picture may be caused by constrictive pericarditis. In the latter instance there will be increased pressure in the cervical veins and in those of the upper extremities, such manifestations being absent in patients with cirrhosis. Likewise, mediastinal tumors may be associated with increased pressure in the veins of the neck and of the arms, but evidence of congestion in the lower part of the body will be absent.

Edema due to renal disease is associated with characteristic changes in the urine. The findings are either those of the nephrotic syndrome, with massive albuminuria, or of acute glomerular nephritis, with hematuria and cellular casts. Hypoalbuminemia is frequently present in minimal degree in patients with chronic cardiac edema but rarely approaches the low values observed in persons with nephrosis and cirrhosis. Patients with acute glomerulonephritis often have both cardiac and renal factors present and operative in the causation of edema. The presence of dyspnea, hypertension, cardiac enlargement, a diastolic gallop and, especially, of improvement following digitalization will usually be sufficient to incite the heart as one factor in the production of edema.

Prognosis is uncertain in patients with chronic cardiac failure. One cannot predict when massive pulmonary infarction, a severe intercurrent infection, or cerebral vascular complications will occur. Despite such uncertainties, several factors are of particular importance in prognosis. The first is the *response to treatment*. The failure of impressive improvement to set in within a few days following vigorous therapy is likely to indicate a grave outlook.

The second factor is the *type of underlying cardiac disease*. When the congestive failure is basically the result of a mechanical lesion such as tricuspid stenosis, mitral stenosis, or constrictive pericarditis, the prognosis is likely to be much better than when the clinical manifestations are the result of a failing myocardium. It is the latter which is responsible for heart failure in patients with com-

nary artery disease and in those with hypertension and aortic valvular disease. Although these latter individuals have a mechanical burden, symptoms do not occur until the left ventricular myocardium has lost its reserve. On the other hand, the pulmonary manifestations of mitral stenosis are dependent on a purely mechanical disorder, as are the systemic congestive manifestations of tricuspid stenosis. Therefore, patients with heart failure due to stenosis of the atrioventricular valves may live for many years in a state of semi-invalidism. This is rarely the case when, as the result of disease or of the mechanical load, the myocardium has to become defective before heart failure develops.

A third important factor in prognosis is the *evaluation of the circumstances under which heart failure develops*. When it has occurred as the result of some circumstance that is particularly amenable to treatment or correction, such as atrial fibrillation with a rapid rate, or respiratory infection, or undue exertion, or the excessive ingestion of salt, the prognosis is likely to be much better than when heart failure has developed in the absence of any such additional stress.

As a general rule, marked cardiac enlargement indicates a gloomy outlook, provided it is mainly due to ventricular enlargement and not to atrial dilatation or pericardial effusion. In the final analysis, however, the response to treatment is the single most important point in prognosis.

TREATMENT OF CHRONIC CONGESTIVE HEART FAILURE

Prevention and Management of Aggravating Factors. The clinical state of patients with chronic cardiac disease does not progress steadily downward but tends to remain stationary or improve slightly for long periods of time, with sudden worsening as the result of various complications. Most of these complications are conditions which cause acceleration of the heart rate and/or increased output. Ectopic tachycardias, with extremely rapid rates, may precipitate failure in individuals with previously good myocardial reserve. However, when the reserve power of the heart is much diminished, even slight degrees of sinus tachycardia may exert deleterious effects. Respiratory infections with the associated distressing cough, physical exertion beyond that which produces dyspnea, fever due to any cause, emotional stress, and anemia are particularly important in this respect. The therapeutic implications are obvious.

Pulmonary infarction, discussed in Chap. 262, is one of the commonest complications. Its likelihood can be reduced by avoiding excessive rest in bed, by permitting some slow walking, by elastic bandages, by alertness in the detection of phlebothrom-

bosis, and by the use of anticoagulants in appropriate instances.

In patients with cardiac disease, *pregnancy* involves a number of special problems, which are discussed later.

Rest and Activity. The initial consideration in the management of the patient with congestive failure is that of placing him in a position in which dyspnea and the consequent metabolic demands of labored breathing on the heart are minimal. In most patients the semirecumbent position in bed meets these requirements. The upright posture favors edema formation in the dependent portions of the body but tends to diminish pulmonary edema, a far more serious condition than peripheral edema.

Ordinarily, the patient with congestive failure should be allowed to get out of bed and walk to a nearby commode for bowel movements. This procedure has the additional advantage of tending to exercise the leg muscles and thereby reduce the likelihood of phlebothrombosis and pulmonary infarction. When for any reason the patient's strength does not permit being out of bed and walking a little each day, anticoagulant drugs, elastic stockings, and passive exercises of the legs plus massage are indicated.

The advantages of the recumbent position are its favorable effects on peripheral edema and on fatigue. On the other hand, this position encourages reabsorption of fluid and thus tends to induce paroxysmal dyspnea. There is some advantage in attempting to induce diuresis by having the patient assume the horizontal position for several hours a day, preferably in the late afternoon provided dyspnea is not induced. When this daily rest period induces diuresis, it should be carried out indefinitely, as long as the activities of the day in the upright position result in the development of more than a slight amount of edema of the lower extremities.

Diet and Fluids. All patients with heart failure should be placed on a low-sodium diet, the extent of the sodium restriction depending on the severity of the cardiac failure. With the elimination of salted foods, the use of sodium-free milk, bread, and butter, and the avoidance of canned vegetables and prepared condiments, diets containing not more than 200 to 400 mg sodium per day can be administered. At the same time it is important to be certain that the water ingested (especially if it is water that has been softened) is poor in sodium and that drugs containing sodium are avoided. This extremely unpalatable type of diet is necessary only for patients with advanced heart failure. In milder instances diets containing 1.0 to 2.0 Gm sodium (2.5 to 5.0 in salt) may be permitted.

When the patient with congestive failure is first seen, anorexia may be so severe as to preclude a

reasonably well-balanced diet. Under these circumstances sodium-free milk (Lanolin) or fruit juices and bananas, containing only minute quantities of sodium, are preferable to the traditional Karel diet (800 ml milk per day, containing about 400 mg sodium) for the first 2 or 3 days. At the end of this time, and as the result of this regime and other therapeutic measures simultaneously instituted, it is usually possible to administer a balanced diet containing not more than 200 to 400 mg sodium (equivalent to about 0.5 to 1 Gm sodium chloride). When compensation is fully restored or when the maximal therapeutic effect has been achieved, some of the dietary restrictions may be lifted. However, it is preferable to insist that the patient remain permanently on a diet containing not more than 1.0 to 2.0 Gm sodium, and considerably less in the case of those individuals whose myocardial efficiency is markedly impaired. The less the sodium intake, the less the tendency for outspoken congestive failure to recur, and the less the need for diuretics.

The various commercial sodium-free substitutes for table salt are considered to be palatable by a few patients. Others prefer vinegar, onion, or lemon juice to overcome the insipid taste of a sodium-poor diet.

The intake of water should usually be regulated by the desire of the patient.

Weight reduction is desirable for obese patients, and thiamine is indicated when there is protracted anorexia even of mild degree. The other vitamins may be given also when the anorexia is both prolonged and severe.

Digitalis. Since this drug constitutes one of the cornerstones of management, it will be discussed in some detail.

Mode of Action. The main effect of digitalis appears to be strengthening of the cardiac muscle with increase in ventricular emptying. Thus the drug tends to overcome the cardinal hemodynamic defect of myocardial failure, which is defective emptying of the ventricles (Chap. 18). In patients with atrial fibrillation, digitalis causes additional benefit by producing pronounced slowing of the ventricular rate by reducing the responsiveness of the junctional tissues to the barrage of impulses arising in the atrium. The slowing of the rate is slight in patients with regular rhythm and appears to be of vagal origin.

Indications. Atrial fibrillation with a rapid ventricular rate constitutes one of the chief indications for digitalis. When the drug is given intravenously as lanatoside C, and when the arrhythmia is of the paroxysmal type and of short duration, normal rate and rhythm are restored in some patients. However, this happens more frequently in patients with paroxysmal tachycardia. In chronic atrial fibrillation

the drug slows the rate without abolishing the abnormal atrial rhythm. Digitalis frequently converts atrial flutter into atrial fibrillation. Therapeutic doses will abolish premature beats in many patients with cardiac failure. Toxic doses produce premature beats, often in the form of bigeminal rhythm or, less frequently, paroxysmal atrial tachycardia with block, ventricular tachycardia, or nodal rhythm. These grave toxic effects usually occur in patients who, because of diuretics or anorexia, are depleted of potassium (p. 1390). Further details concerning digitalis and arrhythmias will be found in Chap. 250.

The most common indication for digitalis is the presence of congestive heart failure, even when the rhythm is regular. When failure is severe, the drug alone is often ineffective, and other measures such as diuretics are needed. However, in the earlier instances, and especially in patients having attacks of paroxysmal nocturnal dyspnea, digitalis alone is usually efficacious in treating and preventing the seizures.

The drug should be used in patients with early failure when the cardiac reserve is diminishing, as indicated by increasing dyspnea for a given effort or by diastolic gallop.

In doubtful instances the value of the drug can be tested by clinical observation of the response, supplemented at times by measurement of vital capacity and circulation time, before and after digitalization. This procedure is occasionally of value in differentiating dyspnea due to cardiac disease from that due to emphysema and other pulmonary disorders. As a rule, a patient should be given digitalis when the exertion incidental to a reasonably active life begins to induce dyspnea.

Once digitalis has been administered for congestive failure, the patient will usually need it either continuously or for long intervals throughout most of his life. The practice, frequently followed, of discontinuing the drug as soon as the overt manifestations of congestive failure have disappeared is not sound.

In some patients with paroxysmal atrial tachycardia, the seizures are prevented by the daily administration of digitalis; in other instances, this procedure is ineffective.

Contraindications. This drug, like any other, is contraindicated under conditions where there is no clear indication for its use. Neither enlargement nor murmurs constitute an indication unless there is dyspnea or edema. It should not be given to patients with sinus tachycardia, except when clear evidence of congestive failure, either actual or imminent, is present.

Digitalis may cause nodal or ventricular tachycardia, or atrial tachycardia with block (p. 1400), and most instances of fatal digitalis intoxication arise from the mistaken assumption that the pres-

ence of the rapid rate in such patients constitutes an indication for larger doses. Bradycardia of moderate degree is often a desirable effect, and the common practice of discontinuing the drug when the heart rate is less than 70 per minute is unsound. In some patients maximal benefit is achieved at resting rates between 50 and 60. In persons with atrial fibrillation it is desirable to administer enough of the drug so that the heart rate after mild exercise also remains within the normal range.

Preparation and Dosage. If one form of digitalis, administered properly, fails to produce improvement, it is unlikely that significant benefit will be obtained by a different preparation. The best results will usually be achieved by the physician who familiarizes himself thoroughly with only two preparations, one a rapid-acting type for emergencies and the other an intermediate or long-acting product for long-term digitalization.

The idea that all patients require about the same dosage of digitalis is mistaken. Actually, there are wide variations. The powdered leaf, about 1.2 to 1.6 Gm in 48 hr, and gitalin (Gitaligin), about 5 to 7 mg in 48 hr, are excellent preparations for most patients who have not been previously receiving the drug. When there is no emergency, the best procedure is to give a patient about two-thirds of the minimal digitalization dose in the first 24 hr. If such a dose causes no improvement, it is unlikely that digitalis will be of much value. If the expected benefit has been achieved, the maintenance dose may be instituted without proceeding to "full" digitalization. If the degree of improvement is less than anticipated, the average maintenance dose may be given three times daily after meals for several days, and then twice daily after meals. The patient should be instructed not to take the drug unless the meal has been eaten and enjoyed. In this way the onset of anorexia, which is usually the initial manifestation of toxic effects, tends to limit the dosage of the drug. The usual maintenance dose is about 0.5 mg gitalin, 0.1 mg digitoxin, or 0.1 Gm powdered leaf.

Many physicians prefer to use digitoxin because the available knowledge concerning its absorption, excretion, and destruction appears to be more precise than in the case of other preparations. Such knowledge indicates that about one-half the daily administered dose is excreted daily and that the destruction is largely independent of dosage and proceeds at a fixed rate for a given patient. If the sum of excretion and destruction is greater or less than the daily intake, the patient will eventually lose the digitalis effect or develop digitalis intoxication. It is probable that the same principles apply to other digitalis preparations, and if so, it is theoretically impossible to maintain a patient in a properly digitalized state on a constant daily main-

tenance dose unless it is almost exactly equal to the sum of the daily excretion and destruction. This dilemma may be avoided by routinely utilizing the average maintenance dose, or slightly less of one of the intermediate preparations (digoxin or gitalin), and giving augmentation doses for a few days every 2 or 3 weeks. The patient is instructed to take the previous daily maintenance dose three times daily after meals and only provided the appetite has not suddenly declined. This procedure is continued until (1) anorexia and/or nausea develops, (2) the physician, who should see the patient daily during this period of augmented dosage, detects frequent premature beats or sudden increase in heart rate, or (3) the desired clinical improvement occurs. In the latter instance, there is no need to continue to the point of toxic effects. Many patients do not require complete digitalization and will improve on this plan without untoward effects.

This third phase of digitalis therapy, i.e., periodic augmentation in addition to the traditional phases of initial digitalization and daily maintenance dosage is of great practical value in preventing the loss of effectiveness of the drug and the consequent worsening of heart failure which otherwise occurs in most patients who are kept on a constant daily dose for a long period of time. However, the procedure is hazardous unless certain precautions are observed. One of these is the concomitant administration of 1 Gm potassium chloride after each meal. This may be given either as tablets or as a 25 per cent solution, 4 ml being added to a large glass of orange juice. The likelihood that serious arrhythmias will precede the annoying but much less dangerous anorexia is thereby sharply reduced. When anorexia and nausea develop it is essential to decide whether these symptoms are due to digitalis or to some other cause such as potassium salts, ammonium chloride, or opiates. Another precaution implies daily observation by the physician during the period of augmented dosage, in order that the exceptional situation in which, despite potassium therapy, the digitalis induced arrhythmias appear first may be detected. A third precaution involves the use of those preparations (gitalin and digoxin) which, while effective by the oral route, have a relatively brief duration of action. They are preferable both for maintenance and for augmentation, because intoxication of mild degree frequently occurs during the periods of augmentation, and the duration of such intoxication is less than when digitoxin or powdered leaf is employed.

When a rapidly acting digitalis is desired, or when one is uncertain as to whether or not the drug should be given and wishes to use a preparation the effect of which will wear off within a few days, *Digitalis lanata* may be administered intravenously. The most satisfactory preparation of

Digitalis lanata is lanatoside C. Its quick onset of action makes it especially valuable in the management of such emergencies as acute pulmonary edema. Its rapid disappearance from the body makes it useful in patients who need digitalis but who are particularly susceptible to its untoward effects. Hence, in a person with myocardial infarction and increasing congestive failure, in whom digitalization may precipitate a serious disturbance of rhythm, this drug is preferable to others of the digitalis group. On the other hand, the rapidity of elimination makes it less desirable for use in the management of the usual patient with congestive failure. The usual total dose of lanatoside C required for digitalization is 1 to 2 mg for adults. This is administered intravenously in divided doses over a period of 4 to 8 hr. When good response is obtained, a longer-acting preparation should be used to maintain the effect. Since lanatoside C is rapidly dissipated, this can be accomplished by giving gitalin 0.5 mg three times daily after meals for about 5 days, and then 0.5 mg once daily indefinitely. The drug is temporarily discontinued if the appetite is lost or nausea develops. In the above plan one may substitute 0.1 mg digitoxin, or 0.1 Gm powdered leaf for 0.5 mg gitalin. The administration of the longer acting preparation is begun about 8 to 12 hr after the final dose of lanatoside C.

In patients who have been receiving digitalis and who have nausea and vomiting, it may be difficult to decide whether these symptoms are the result of abdominal congestion and constitute an indication for additional digitalis, or whether they represent toxic effects from overdosage. Under such circumstances the use of acetylstrophanthidin has been proposed. However, this is a hazardous procedure. In the usual patient the same information can be obtained by stopping digitalis therapy for a few days and noting whether the clinical state improves, as will occur if digitalis intoxication has been present.

Manifestations of Digitalis Intoxication. The most important of these include gastrointestinal disturbances—i.e., anorexia, nausea, and vomiting, developing in that order—and disturbances of the cardiac rhythm, of which the frequent premature beat, usually in the form of bigeminal rhythm, and atrial tachycardia with block are the most common. Inversion of the T waves and slight increase in the P-R interval are normal effects of the drug. Severe degrees of heart block due to digitalis intoxication occur frequently in animals but are very rare in man unless there is preexisting conduction impairment. In an occasional patient the drug converts sinus rhythm into atrial fibrillation. The reverse effect—conversion of atrial fibrillation to normal rhythm—may occur when the arrhythmia is of recent onset. Nodal rhythm with moderate to marked

tachycardia occasionally appears, and ventricular tachycardia may develop, with danger of ventricular fibrillation if the administration is continued. Less common toxic effects include diarrhea and xanthopsia (yellow vision).

When doses within the therapeutic range are employed and potassium depletion is avoided, the only common toxic effects are anorexia, nausea, and bigeminal rhythm, all of which disappear within a few days after withdrawal of the drug. Since it is often desirable that the drug be pushed to the onset of the minor toxic effects, it is well to warn the patient that vomiting may occur. Such warning not only will alleviate anxiety if vomiting does appear, but will make the patient more alert to report the onset of anorexia, which is usually the initial and the most benign indication that the toxic effect has developed. However, it is important to remember that the more serious toxic effects may supervene without the preliminary appearance of the usual warning signals in the form of the milder manifestations of toxic action.

Premature beats, or other arrhythmias, when induced by digitalis, may be improved by the oral administration of potassium salts (Chap. 250). Such arrhythmias are especially likely to be caused by digitalis when there is potassium depletion as the result of the frequent use of diuretics. Since glucose ingestion causes decline in plasma potassium, the toxic arrhythmias due to digitalis should be sought especially carefully during the period of 30 to 60 min after a carbohydrate-rich meal. When digitalis intoxication is present or imminent, protein-rich, carbohydrate-poor meals are indicated, and potassium chloride (1 Gm three to six times daily) should be administered orally unless renal insufficiency is present.

The most important principle of digitalis therapy is to push the drug until the patient exhibits either the desired therapeutic action or definite evidence of toxic effects. This is only another way of saying what William Withering, who introduced the drug into medical practice, stated so clearly: "Let the medicine . . . be continued until it either acts on the kidneys, the stomach, the pulse, or the bowels, let it be stopped upon the first appearance of any of these effects."

Diuretic Drugs. The rational use of these valuable agents depends upon an understanding of their effects on the disturbances of renal function responsible for the retention of sodium and of water. Although knowledge of these disturbances is still incomplete, it would appear that there are at least three different but related mechanisms which call for different treatment. One of these is the increased reabsorption of water and sodium in the proximal tubules, which appears to be dependent in some measure on hemodynamic factors and, especially,

on the high filtration fraction which produces an abnormally high oncotic pressure in the blood of the peritubular capillaries. Unknown enzymatic reactions are probably also concerned. The commonly employed diuretic drugs such as chlorothiazide and the mercurials tend to block the proximal reabsorption not only of sodium and of chloride but also of potassium. They, therefore, cause diuresis but also often lead to *potassium depletion which is not necessarily reflected in the plasma potassium level.*

Another mechanism responsible for increased reabsorption of sodium and water is the excessive formation of aldosterone, which is believed by some to act chiefly on the *distal tubules*. Spironolactone (Aldactone), which is an aldosterone antagonist, blocks this action. However, if its main action is distal, it can be effective only when significant quantities of sodium are delivered to the distal tubule. Thus if most of the sodium should be reabsorbed in the proximal portion, spironolactone would be of little value. This is a possible explanation for its frequent ineffectiveness. However, it may be useful as an adjuvant to the conventional diuretics which block proximal reabsorption. Actually, because of its expense, this drug should be reserved for patients who display an inadequate response to other diuretic measures. Spironolactone, unlike chlorothiazide and mercurials, does not tend to induce potassium deficit.

A third and probably less common renal mechanism is the retention of excessive quantities of water in response to the antidiuretic hormone or to some substance having a similar action. This is probably one factor in the production of the serious "dilution syndrome," which is considered later.

All patients who have ever suffered from edema of cardiac origin and who have a tendency toward recurrence should weigh themselves each day under standard conditions. As a rule this means weighing in the morning immediately after rising and emptying the bladder, without clothing other than slippers and pajamas. The written record of such daily weighings constitutes the guide to therapy by diuretic drugs.

The most generally useful diuretics are those of the chlorothiazide group. They are indicated when the weight record shows a rapid increase. Since anorexia is common in patients with congestive failure, the effects on body weight of expansion of extracellular fluid volume may be masked by concomitant loss of flesh. Therefore, even though the patient's weight is stationary, chlorothiazide is needed when there is progressive swelling of the ankles, or whenever there is a sharp increase in the degree of dyspnea.

A generally suitable plan is to administer 250- to 500-mg doses of chlorothiazide two to four times daily for five successive days out of each week, as

long as the above-mentioned indications exist. Because of the strong tendency for potassium depletion to occur, potassium chloride should be also administered, as already described (p. 1388). This is especially important when the normal dietary intake of potassium is limited because of anorexia. When there is persistent oliguria or grave impairment of renal function, potassium administration may be hazardous and should be controlled by repeated measurement of the plasma level.

Since the advent of the chlorothiazide group of drugs the mercurial diuretics are needed much less frequently than formerly. They should be reserved for patients with massive edema, in whom especially profuse diuresis appears desirable, or for persons who fail to respond well to chlorothiazide.

Convincing evidence that any one of the currently available mercurial preparations is superior to the others is lacking. The initial dose should be 1 ml intramuscularly. If a satisfactory diuresis is not produced, 2 ml is given, and this dose may be repeated after several days. Unless renal function is seriously impaired, it is well to administer potassium chloride (3 to 4 Gm per day) routinely, and to add ammonium chloride for 3 days when a mercurial diuretic is to be administered. The effectiveness of the latter is sometimes enhanced by the prior injection of aminophylline intravenously.

When these measures fail, spironolactone may be used in conjunction with chlorothiazide or mercurial diuretics. It is likely to be ineffective if administered alone (see above), is expensive, and is only rarely needed.

The untoward effects of diuretics fall into several categories, the most important being those related to *electrolyte depletion* of different types. These electrolyte disturbances are likely to occur in persons whose salt intake has been severely restricted and who have received vigorous mercurial therapy with massive diuresis. Aside from refractoriness to diuretic drugs, there may be no symptoms, or there may be a group of symptoms common to all, regardless of the electrolyte patterns; lassitude, apathy, mental confusion, anorexia, decrease in urine volume, and azotemia. When adequate facilities are available, frequent measurement of the serum levels of sodium, potassium, chloride, and carbon dioxide as well as of urea should be carried out, especially when congestive failure does not respond to adequate therapy.

When water, chloride, and sodium are excreted in excessive quantities but in ratios similar to those present in normal serum, a state of *absolute extracellular fluid deficit* with dehydration may occur. A somewhat analogous disorder is the *distributional disturbance of extracellular fluid*. This occasionally appears in individuals who continue to have edema of the legs because of the orthopneic position but

who, as the result of diuretic drugs, have a deficiency of extracellular fluid in the upper parts of the body. In such patients the diagnosis rests on the clinical manifestations of dehydration (p. 459) in the affected areas. Measurements of plasma electrolytes yield normal values, but urea nitrogen is usually elevated. The treatment consists of the administration of salt-enriched foods. Only rarely is parenteral administration of sodium chloride solution necessary.

More common and more serious are those disorders characterized by lowered concentration of sodium and chloride in the plasma. These may be induced by (1) disproportionate urinary loss of electrolytes as compared to water during diuresis; (2) retention of excessive volume of water by the kidneys, probably as the result of the action of the antidiuretic hormone or of related substances, or (3) a shift of chloride and sodium from the extracellular to the intracellular fluid. Two entirely different disturbances may occur, and their distinction is of practical importance in treatment.

The *salt depletion syndrome* is closely related to the disorders of extracellular volume which have been mentioned above, but differs from them in exhibiting low values for the plasma sodium and chloride. It usually is seen when edema is absent or minimal; evidence of extracellular fluid deficit is commonly observed in the upper part of the body. The ingestion of salt-enriched food or the cautious daily intravenous infusion of 200 to 300 ml of 5 per cent sodium chloride will overcome the symptoms within a few days.

The *salt dilution syndrome* presents the same electrolyte pattern, with low sodium and chloride levels, but this condition is more grave and appears to develop through a different mechanism. It is usually encountered in markedly edematous patients during the late stages of heart failure as well as in a variety of other unrelated terminal illnesses, even when there have been no unusual losses of salt. Hypertonic sodium chloride is rarely of benefit in these patients, and although the plasma electrolyte pattern may be temporarily corrected, thirst is aroused, further excesses of water are retained, the serum sodium and chloride levels fall to their previous levels, and the net result is an increase in the extracellular fluid volume with further increase in edema. The proper treatment is marked restriction of water intake, thus allowing the insensible water loss to repair, in time, the relative electrolyte deficit.

Another important electrolyte disturbance, stemming primarily from diuresis, is *hypochloremic alkalosis* due to the disproportionate loss of chloride and of potassium. Body stores of potassium are usually depleted even though serum potassium may be normal. Serum chloride is abnormally low, bi-

carbonate is correspondingly elevated, and sodium remains normal or at near-normal levels. Exactly the same chemical findings occur in respiratory acidosis, and differentiation between the two must be made on clinical grounds unless means for accurate measurement of the plasma pH are available. Respiratory acidosis occurs when the primary cause of the difficulty is a pulmonary disorder such as obstructive emphysema, interfering with O_2 and CO_2 exchange, or a depression of ventilation (e.g., morphine or sedatives) acting in essentially the same way. The treatment of hypochloremic alkalosis consists of the administration of ammonium chloride, 4.0 to 6.0 Gm per day in divided doses or, when oral administration is not possible, by the slow intravenous infusion of a 1 per cent solution of ammonium chloride, at a rate not greater than 100 ml per hr. A total of 500 ml may be given on one day and repeated the next, if necessary. The effect of acetazolamide (Diamox) is very similar to that of ammonium chloride, and the combined effect of acetazolamide, 250 mg t.i.d., and ammonium chloride, 4.0 Gm per day, may bring about a fairly rapid restoration of chloride to normal levels. Potassium chloride, 1.0 Gm four times daily, should be given orally, since a potassium deficit practically always accompanies hypochloremic alkalosis.

Potassium deficiency in the absence of alkalosis may occur following the prolonged use of diuretics, particularly when there have been additional losses of potassium by vomiting or diarrhea, and when anorexia has limited the supply of food. The chief manifestations, in addition to those described above as being common to all electrolyte disturbances, are unusual muscular weakness, abdominal distention due to intestinal atony, and electrocardiographic alterations: progressive depression of the S-T segment and rounding, lowering, and inversion of the T wave; increasing amplitude of the U wave in the left precordial leads. It is important to bear in mind that serious potassium deficits may exist even though the serum potassium level may be normal, and such a deficiency should be presumed to exist when ammonium chloride or acetazolamide has been administered, when hypochloremic alkalosis occurs, and particularly when unexpected digitalis intoxication develops.

Refractoriness to diuretics represents a grave situation. Potassium deficit is probably the commonest cause. When such refractoriness is not responsive to potassium salts alone, it can often be overcome by the production of hyperchloremic acidosis. For this purpose ammonium chloride (8 Gm daily in divided doses) is given for 5 days. Unless the patient is eating normally, potassium chloride (4 to 6 Gm daily) should likewise be prescribed. During the first 3 days of the regime, acetazolamide is administered in doses of 250 mg

twice daily. On the fifth and several subsequent days, mercurial diuretics are administered. In doubtful instances blood chloride and carbon dioxide combining power should be measured daily and the acetazolamide and ammonium chloride administration continued until the respective values are significantly altered. In some patients it appears to be necessary to achieve levels of 120 mEq per liter or more for chloride and 20 mEq per liter or less for bicarbonate, before the refractoriness can be overcome.

Other Therapeutic Measures. Sedatives. The judicious administration of sedatives is helpful, especially in the early days of severe congestive failure. For dyspnea, morphine (10 to 20 mg) or Pantopon (10 to 20 mg), administered parenterally, is usually effective in affording some degree of comfort and in ensuring sleep. They are best given in the evening and, after 4 hr or more, repeated once during the night if necessary, but always with due regard for the caution necessary in the use of these drugs in the aged, and for the dangers of habituation if they are used for more than a few days. Aside from promoting sleep, opiates are valuable because they reduce the strenuous work of the respiratory muscles. They also enable the patient to assume the recumbent position, which often initiates diuresis. After the first few days, when congestive failure has been considerably alleviated, moderate amounts of barbiturates may be substituted. During the day the meprobamate tranquilizing drugs or small doses of phenobarbital (15 to 30 mg), two or three times daily, may diminish undue restlessness and apprehension. *It is most important, however, that one be particularly careful to avoid excessive sedation because of the possibility of rendering the patient so lethargic that he is unwilling or unable to participate in sufficient activity to minimize the danger of phlebothrombosis, and because of the undesirability of excessive respiratory depression in a patient with lowered vital capacity.*

Venesection. Seizures of acute pulmonary edema constitute the most important indication for venesection, which is a rapidly effective and often a life-saving procedure under these circumstances (p. 1383). Venesection is usually beneficial in patients with chronic cor pulmonale who have hematocrit values of 50 per cent or more. Painful congestion of the liver may likewise be benefited. Venesection may be employed in all patients with intractable heart failure, but under such circumstances lasting benefit is rarely produced. Ordinarily, the amount of blood removed should be 300 to 400 ml for an adult patient of average size without anemia.

Oxygen. Administration of oxygen is indicated (1) in any patient with evidence of outspoken arterial hypoxia, (2) when dyspnea is severe, and (3) possibly in patients with intractable congestive

failure. When oxygen is needed for several days, a tent is the most useful method of administration; for periods of a few hours, a mask is convenient, effective, and relatively inexpensive (Chap. 268).

Thoracentesis. This is a valuable procedure in many patients with congestive failure. It should be employed in all severely dyspneic patients who present evidence of hydrothorax. Abdominal paracentesis is indicated whenever ascites is prominent and fails to respond promptly to sodium restriction and diuretics.

Puncture of the Legs. In those few patients who respond poorly to properly used diuretic measures, edema may be overcome by puncturing the skin of each leg 10 or more times with an 18-gauge needle. The patient should then remain in the sitting position for 12 hr or more and should be given appropriate antibiotics, usually penicillin, to prevent infection.

Special Problems in the Management of Heart Failure

Pregnancy. The physiologic adjustments that normally take place during pregnancy, the increase in heart rate, cardiac output, and blood volume place a burden on the cardiovascular system. This burden, unlike that due to muscular effort, is present continually, both night and day. It reaches its peak at about the seventh or eighth month of pregnancy. Thereafter, these functions decline and tend to approach normality up to the time of labor. This hyperkinetic state of the circulation acts to diminish the cardiac reserve, a reduction of which is well tolerated by the pregnant woman with the normal heart, but is tolerated with varying degrees of success by the woman with organic heart disease, depending on the extent to which her cardiac reserve has already been diminished by the structural lesion of the heart. *The greatest danger of congestive failure to the woman with heart disease occurs at the seventh or eighth month of pregnancy.*

The increase in blood flow through the heart is frequently responsible for the appearance in normal persons of functional systolic murmurs which, with the edema of the ankles, that is also not uncommon, and the displacement of the cardiac impulse by the elevated diaphragm and the resulting mistaken impression that there is cardiac enlargement, sometimes may give rise to the erroneous idea that heart disease is present. The increased blood flow also tends to accentuate murmurs in those who do have organic heart disease, thus occasionally revealing for the first time a hitherto undetected lesion such as mitral stenosis. Though there is no diminution in vital capacity, ventilation increases and the respiratory reserve is curtailed, thus facili-

itating the appearance of dyspnea with any given effort.

The chief practical problems presented by pregnancy in relation to heart disease are as follows:

(1) Should the woman with cardiac disease become pregnant? (2) What should be done about a woman already pregnant who presents evidence of cardiac disease? In general, these questions are answered by an assessment of the patient's functional capacity, and this, in turn, is best determined by estimation of the symptoms caused by varying degrees of activity. The patient who is asymptomatic or whose dyspnea is minimal even with strenuous exertion can undertake pregnancy with practically no more risk than can the woman with a normal heart. On the other hand, the presence of relatively severe symptoms with ordinary activity, a history of hemoptysis (indicating the probability of an already significantly elevated left atrial and mean pulmonary capillary pressure), or a previous history of congestive failure makes it inadvisable that pregnancy be undertaken and may indicate that the pregnancy should be terminated. The same advice should be given if atrial fibrillation is present, not because of the deleterious effects of the abnormal rhythm, but rather because its presence indicates that an advanced stage of rheumatic heart disease is already present. Nevertheless, even atrial fibrillation is not an absolute contraindication to pregnancy or its continuation to term, provided the functional capacity of the heart is deemed to be reasonably good, the desire for the child great, and the risks understood by the parents. It is the intermediate group of patients, those with symptoms on moderate activity, who present the most difficult problem, the decision depending on a multitude of factors aside from the status of the heart: the number of children in the family, the economic circumstances, the opportunity for restriction of activity, the likelihood that the patient will cooperate in reducing the preventable stresses on the heart, the willingness to accept a calculated risk, etc.

Since the patient with heart disease starts out with the handicap of a diminished cardiac reserve which is still further lessened by the normal physiologic adjustments of pregnancy, all other stresses that confer additional burdens on the heart and circulation require meticulous attention: avoidance of overexertion and emotional tension, correction of anemia, careful supervision of even minor infections, correction of obesity, restriction of salt intake, prompt treatment of abnormal rhythms—especially tachycardias—and frequent search by the physician for early signs of pulmonary congestion.

Termination of Pregnancy. If the patient is already pregnant and falls into one of the unfavorable categories, or if manifestations of congestive failure

appear early, termination by the vaginal route should be carried out during the first trimester. After this time, disposition of the patient is a matter of judgment and always entails uncertainty and risk. If the symptoms are mild or moderate, the patient may with careful medical supervision be carried beyond the critical seventh or eighth month, after which the danger diminishes. On the other hand, if the symptoms are severe, termination of the pregnancy may be considered imperative, the method being left to the obstetrician.

Once a patient has arrived at term, the route of delivery should be decided by the obstetrician on obstetric grounds. Usually, spontaneous delivery aided by low forceps is preferable. Resort to cesarean section as a routine measure is no longer considered desirable, this mode of delivery being reserved only for women who are expected to face a difficult and exhausting labor.

The above comments are applicable in a general way to all women with heart disease, but they refer particularly to women with rheumatic heart disease and mitral stenosis, since they constitute the bulk of those with heart disease in pregnancy. Mitral commissurotomy has been successfully employed in some women in whom threatening symptoms have appeared during pregnancy. It is generally believed, however, that medical supervision alone or termination of the pregnancy is preferable, operative dilatation of the valve being reserved for a later time when the patient is not pregnant.

Patients with the cyanotic types of congenital heart disease usually do not survive until the child-bearing age. When they do become pregnant, the hazard is high and early termination is likely to be indicated. Usually, pregnancy in the patient with acyanotic congenital heart disease is well tolerated. Repair of coarctation of the aorta should be done prior to pregnancy. The occasional development of dissecting aneurysm during pregnancy or of a cerebral vascular accident during delivery makes this condition somewhat more hazardous than other asymptomatic cardiac disorders. Advice regarding future pregnancies will depend on the course of the preceding ones and on the state of the heart at the time the next pregnancy is contemplated.

Intractable Heart Failure. From time to time physicians encounter patients with cardiac failure who either do not show a satisfactory initial response to therapy or who, having previously responded well, become progressively more refractory to management. Under these circumstances the physician will do well to ask himself the following questions: (1) Is the therapy adequate? (2) Is there in this patient an unrecognized etiologic factor which might be treated successfully? (3) Is some complication making the patient respond so

poorly? (4) Is the intractable heart failure due to extreme myocardial impairment? These questions will now be considered in some detail.

1. *Has the patient received adequate therapy for congestive heart failure?* Is the dose of digitalis properly adjusted? If the patient has been receiving a constant maintenance dose of any digitalis preparation, there is a definite possibility that he has escaped digitalization because the combined effects of excretion and destruction of the drug have exceeded the daily maintenance dose. Under these circumstances it is frequently desirable to administer for a few days one of the intermediate drugs, such as gitalin or digoxin, in a dose equal to two or three times the average maintenance of such a preparation (p. 1387).

Digitalis intoxication is likewise a common cause of what may appear to be intractable heart failure. The presence of undoubted signs of such intoxication in an individual who has been receiving a relatively small maintenance dose makes it highly probable that potassium deficit has occurred as the result of anorexia and the frequent administration of thiazide diuretics. Under such circumstances rapid improvement may follow the administration of potassium chloride, 3 to 6 Gm daily in divided doses, for a few days. If the maintenance dose of digitalis has been relatively large, then the patient may be suffering from digitalis intoxication, even though there is no potassium deficit. Careful inquiry should be made concerning the presence of anorexia, nausea, and arrhythmias due to digitalis, and the less frequent and less obvious manifestations of digitalis intoxication such as diarrhea, blurring of vision, and xanthopsia should be sought. If the patient has been receiving one of the intermediate drugs, the manifestations of digitalis intoxication will disappear within 3 to 6 days after withholding it. If powdered leaf or digitoxin has been employed, improvement may be delayed for as long as 1 to 2 weeks after discontinuing digitalis.

Defective restriction of sodium is another common cause of apparent intractability. A patient may religiously refrain from adding salt at the table or during cooking and yet fail to realize that the bread he eats and the water he drinks may be excessively rich in sodium. The physician should be familiar with the sodium content of the tap water in his community and should prescribe distilled water whenever necessary. Sodium-free bread and butter are now available at most large grocery stores.

2. *Is there an unrecognized etiologic factor which might be successfully treated?* One thinks first of all of masked thyrotoxicosis. This condition may present none of its usual clinical manifestations when occurring in an elderly patient with congestive heart failure. The physician should entertain a high

degree of suspicion toward such physical signs as unusual softness of the skin, excessive sweating, frequent bowel movements, heat intolerance, unexplained tachycardia, etc. Even with a high index of clinical suspicion, patients with thyrotoxicosis will be overlooked unless one makes it a rule to determine the protein-bound iodine of the serum in all patients with congestive failure, and particularly in those with atrial fibrillation.

Chronic arterial hypoxia due to primary disorders of the lung is frequently complicated by congestive heart failure and may be strikingly benefited by oxygen therapy properly administered. Anemia of clinically significant degree is usually obvious upon inspection of the patient's skin and mucous membranes, but it may be overlooked. The possibility of thiamine deficiency due to the long-standing anorexia induced by abdominal congestion should be considered in every patient with congestive heart failure. The suspicion should be particularly strong when treating elderly men who live alone or individuals who partake freely of alcohol. In the younger group of patients with valvular disease the possibility that smoldering rheumatic myocarditis or bacterial endocarditis is present should be kept constantly in mind.

It is perhaps even more important to look for evidences of those types of cardiac disease which are particularly amenable to surgical management. Mitral stenosis may be readily overlooked in a middle-aged or elderly patient with atrial fibrillation. The presence of obvious congestive failure may keep the physician from a careful search for such congenital disorders as coarctation of the aorta and patent ductus with a systolic murmur only. Constrictive pericarditis is especially likely to be missed unless constantly kept in mind.

3. *Is there a hitherto unsuspected complication?* In patients who have been subjected to repeated diuretics plus a long-standing low-salt diet, and more particularly, if anorexia has been an important symptom, one should be on constant watch for those electrolyte disturbances already discussed. They are likely to manifest themselves by the relatively rapid onset of refractoriness to diuretics and by the simultaneous appearance of marked lassitude and apathy. In the absence of some serious primary disease of the kidney or of some obvious grave intercurrent disorder, the presence of refractoriness to diuretics constitutes strong evidence for the presence of one of these electrolyte disturbances.

Advanced renal disease frequently is present in patients with congestive failure and especially in those who have either hypertension or bacterial endocarditis. During the initial phase of management the manifestations of congestive failure may overshadow those of the less obvious but often more

serious renal disease. The coexistence of nitrogen retention and of a urine of low specific gravity, despite a small urine volume, makes it highly probable that there is grave functional impairment of the kidneys and that the management of the cardiac failure and, more particularly, of electrolyte disturbances will be relatively unsuccessful.

Pulmonary infarction, discussed in Chap. 262, is one of the commonest causes of intractable heart failure. If this complication is recognized and vigorously treated either with anticoagulants or, in suitable cases, by venous ligation, the heart may again respond to treatment after a period of days or weeks has elapsed. In many instances the expected manifestations (pleural pain, hemoptysis, and changes in the x-ray) will be absent and the sole clues to pulmonary infarction may be unexplained elevations of temperature, leukocyte count, or sedimentation rate, plus aggravation of the cardiac status and, at times, an evanescent increase in the serum bilirubin values or frank jaundice.

4. *Is the intractable heart failure due to extreme myocardial impairment?* This suspicion should be entertained seriously only after the problem has been approached from the standpoint of the questions above. Once one is satisfied that the therapy is entirely adequate, that there is no complicating unrecognized etiologic factor and no serious complication, one is justified in entertaining the question of myocardial disease so advanced that the heart failure has become and will remain intractable.

250 ARRHYTHMIAS

William H. Resnik and
T. R. Harrison

The normal stimulus for the heartbeat arises in the sinoatrial node, spreads through the atrial musculature, traverses the AV node (node of Tawara), the AV bundle (bundle of His), through the Purkinje fibers of the left and right bundle branches, and finally through the ventricular musculature. When this orderly and regular sequence is disturbed, or when the rate of conduction of the impulse is abnormal, a variety of disorders of the heartbeat may follow, the most common and important of which are discussed here. Almost all of these disorders may be the result of structural disease of the heart, but most of them may also be encountered in normal, healthy persons in whom no evidence of organic heart disease is ever discovered or who reveal no abnormalities by histologic examination at autopsy. The most precise method of diagnosis of the various arrhythmias is by electrocardiographic examination. However, the physician who has regularly correlated his observations by simple examination with electrocardiographic tracings can usually recognize most of the arrhythmias by auscultation alone.

Mechanism of Arrhythmias. The hypotheses so widely accepted but a short time ago regarding the pathogenesis of the various arrhythmias are no longer considered as established beyond question. For example, for a number of years the circus movement as the explanation for atrial flutter and fibrillation seemed to have been indisputable, only to be replaced by the concept that these ectopic rhythms were the result of very rapid and irregular stimuli being discharged from a single focus. Actually, this latter view was simply an elaboration, based on rather extensive experimental work, of a hypothesis that had preceded that of the circus movement. At the present time, there is abundant evidence in favor of and in refutation of both concepts, and it is probable that neither is strictly true. Moreover, it is likely that from the newer studies on alterations of the myocardial cell, cell membrane,

and cellular environment and the abnormalities of electrical potential, conduction, and excitability resulting from these ionic disequilibria and disturbances in myocardial cellular metabolism, will come a truer knowledge of the mechanisms of the various arrhythmias and of the manner in which they are influenced by drugs and other procedures.

The value of the electrocardiographic tracings in the differential diagnosis of the tachycardias is obvious. Since registration of atrial activity is particularly desirable, records should be obtained from the right of the sternum, and in many instances while carotid sinus pressure is being applied. At times, the use of esophageal leads may demonstrate P waves not clearly seen in conventional leads, and thus clarify the nature of the tachycardia.

Harmful Effects of the Arrhythmias. The influence of changes of rate on coronary flow and the cardiac output has been described in some detail in a previous chapter (p. 33). It will suffice here to state that, when the heart rate is 30 or more, the bradycardias cause no significant alterations in coronary flow or cardiac output. The danger of a bradycardia exists when it is due to a high-grade partial or to a complete AV block caused by a lesion affecting the AV node or bundle. The ventricular rate may suddenly diminish to 5 to 10 per minute or may come to a complete standstill for 15 sec or more; or ventricular fibrillation may develop, the effect being essentially the same as that of ventricular standstill; circulation to the brain becomes inadequate, syncope of varying degree occurs, and when effective circulation halts for 15 sec or longer, convulsions appear. These attacks are known as Stokes-Adams attacks, and a person subject to them is always in danger of sudden death.

Because diastole is abbreviated to a greater extent than is systole in a tachycardia, the effect of a rapid increase in rate is to increase oxygen consumption of the heart and to diminish coronary flow. When the rate of an ectopic tachycardia is 160 or more, and there is no concomitant increase in cardiac output such as would occur if strenuous exercise induced a heart rate of this magnitude, the efficiency of the heart is reduced, cardiac output declines from its previous normal level at rest, and cerebral blood flow diminishes. In brief attacks, this may result only in a sense of fluttering in the chest or neck, or the patient may be quite unaware of the ectopic rhythm, or he may experience a sense of faintness in the upright position. In longer attacks, depending on the age of the patient, on the presence or absence of some other form of structural disease of the heart, and on the ventricular rate, cardiac output may fall to a level where the characteristic features of forward failure appear with cool, moist, pallid skin and diminished pulse pressure; or cardiac reserve may be reduced and failure

may appear; or angina or myocardial infarction may develop, if the patient has a condition that predisposes to myocardial ischemia. Occasionally, fever may occur with the tachycardia, owing to the disturbed dissipation of heat caused by the peripheral vasoconstriction, and when this is associated with leukocytosis, angina, and infarction-like T waves which may persist for many days following the cessation of the attack, confusion with myocardial infarction is a possibility. *The harmful effect of tachycardia is most strikingly apparent when the heart is already badly damaged, as in acute myocardial infarction, and there should be no delay in instituting the most effective measures of therapy.* Even extrasystoles, when they are frequent enough, may exert the same harmful effects as tachycardia, though to a lesser degree. Moreover, there is evidence that a paroxysmal ventricular tachycardia magnifies the harmful effects of rapid heart rate because the ventricular impulse, pursuing an abnormal course, gives rise to a relatively ineffective contraction.

Drugs in Arrhythmias. Since the same agents are employed in many of the arrhythmias, their description will be given here to avoid repetitiousness.

Pressor Amines. When an ectopic tachycardia is associated with hypotension and the usual antiarrhythmic agent is ineffective, the additional administration of a pressor amine, such as *phenylephrine (Neo-synephrine)*, 0.5 to 1.0 mg diluted in 10 ml saline and given slowly intravenously, may terminate the tachycardia. Such treatment alone is frequently effective in *paroxysmal atrial tachycardia*, especially when the blood pressure has fallen appreciably as a result of the tachycardia. Blood pressure observations are made while the drug is being given, and one endeavors to increase the pressure to about 160, not more, an admonition that is important in older persons. Control of hypotension is especially urgent when an ectopic rhythm complicates acute myocardial infarction with shock, an extremely critical condition. All the pressor amines tend to induce ectopic rhythms, but experience appears to indicate that this tendency is not great and that their advantages outweigh the disadvantages.

LEVARTERENOL (LEVOPHED). When an ectopic rhythm occurs in *myocardial infarction* with shock or in any other disorder with profound hypotension, levarterenol is the pressor amine most commonly employed, because it is the most potent and its action is prompt and evanescent. Consequently, its effect can be accurately titrated by the rapidity of administration. It must be given by intravenous drip (4 to 8 mg per liter 5 per cent glucose), the blood pressure frequently observed, and care taken to prevent extravasation into the subcutaneous tissues. Should extravasation occur, 5 mg phenolamine (Regitine) diluted in 20 ml water and infiltrated

throughout the involved tissues will prevent necrosis. If some other antiarrhythmic agent must be given simultaneously (e.g., procaine amide, Pronestyl), the flask containing the latter can be connected with a Y tube to the levarterenol infusion, and each drug can be given at its own rate independent of the other. This leaves the other arm free for blood pressure determinations, and electrocardiographic monitoring can be carried out at the same time. One endeavors to maintain the systolic level at 100 to 120 in a normotensive person and 120 to 160 in a person previously hypertensive. Metaraminol (Aramine) and mephentermine (Wyamine) may be given subcutaneously or intramuscularly, 3 to 15 mg, the exact dose and frequency depending on the behavior of the blood pressure. Acidosis renders the vasculature less responsive to the pressor amines, and this should be corrected with molar sodium lactate (p. 471).

Sympathomimetic Drugs. The pressor amines are also sympathomimetic drugs, but those mentioned in the previous paragraph are given primarily for the purpose of elevating the blood pressure. The agents now to be discussed are used primarily to increase the rhythmic activity of the myocardial cells, and they are the mainstay of the management of the patient with *heart block* and *Stokes-Adams attacks*. *Isopropylnorepinephrine* (*isoproterenol*, *Isuprel*) is the most widely used since it is considered least likely to provoke a serious ectopic rhythm, its predominant effect being the stimulation of the higher ventricular and nodal tissues rather than the excitation of lower ventricular foci. When the exact mechanism of the Stokes-Adams attack is uncertain, isoproterenol is considered the safest drug available. This may be given intravenously, 4 mg per liter 5 per cent glucose, and the dosage titrated to give a ventricular rate of about 50. It may also be given subcutaneously 0.2 mg every 1 to 2 hr, or sublingually, 10 to 15 mg several times a day. The mode and frequency of administration will depend on the particular circumstances of the illness. *Epinephrine*, aqueous (0.3 ml of 1:1,000 solution every hour) or suspended in oil for a more prolonged effect (2.0 mg three to four times daily) may be used. A convenient oral preparation is a capsule containing *ephedrine* 0.025 Gm and *Amytal* 0.05 Gm which is given several times a day.

Digitalis. Lanatoside C (Cedilanid) is a satisfactory preparation for the treatment of any of the *supraventricular paroxysmal tachycardias* excepting, of course, paroxysmal atrial tachycardia with block, usually caused by digitalis intoxication. This may be given intramuscularly or intravenously, 0.8 to 1.2 mg with additional doses of 0.4 mg at half-hourly intervals until the desired result is obtained and not exceeding a total of 2 mg. These amounts are based on the presumption that the patient has had no

digitalis during the preceding 2 weeks. For the control of *established flutter and fibrillation*, digitalis is employed in the usual manner (p. 1387).

Quinidine. This drug has a place in the management of practically all *ectopic arrhythmias* that require treatment, although it is not necessarily the first choice except in the *ventricular arrhythmias*. *Quinidine should never be employed in the presence of high-grade block*. In all persons, the use of quinidine introduces a small risk of sudden death, the mechanism of which is unknown, for autopsy investigation has never revealed any structural lesion that could account for the fatality. It is our conjecture that the mechanism of sudden death is similar to that in myocardial infarction and probably due to ventricular fibrillation or standstill. The risk of embolism is about $\frac{1}{2}$ per cent in patients with atrial fibrillation. There is still a difference of opinion regarding the hazards of quinidine therapy when the patient has a bundle branch block. The appearance of syncope is an indication for the prompt discontinuation of the drug since the mechanism of the syncope is probably intimately allied or identical with that responsible for sudden death. Nausea, vomiting, diarrhea, allergic skin rashes, purpura are other untoward manifestations that may necessitate cessation of the use of the drug. It is essential to bear in mind that quinidine is a myocardial depressant, that intravenous administration should be employed only under the gravest circumstances, and that intramuscular therapy, too, should be given cautiously. It is customary to give a preliminary dose of 0.2 Gm to determine the presence of hypersensitivity. Quinidine sulfate 0.2 Gm is given four times a day as a maintenance dose or for the control of *premature beats*; or the long-acting quinidine gluconate (*Quinagluce Dura-Tab*) 0.3 Gm may suffice in only two or three doses per day. For a more intensive course of therapy, as in the attempted conversion of *chronic atrial fibrillation*, the patient is first fully digitalized, and quinidine 0.2 Gm every 2 hr for five doses is given on the first day. If, by the following morning, fibrillation persists, 0.4 Gm is administered in the same way and, if necessary, 0.6 Gm on the next. When 0.4 or 0.6 Gm is given, electrocardiograms should be taken prior to each dose of the drug. Quinidine is discontinued if the QRS increases by 50 per cent over the control or if numerous ventricular premature beats occur and, obviously, if ventricular tachycardia develops. Intramuscular quinidine, the hydrochloride or gluconate or lactate, may be given according to these schedules, if one deals with a more urgent problem such as *ventricular tachycardia*. These preparations, 1.0 Gm diluted in 100 ml 5 per cent glucose, may be used intravenously. If quinidine intoxication develops, the most effective therapy is molar sodium lactate given intra-

venously, 100 ml followed by 50 ml every 30 min until the signs of toxicity disappear, more than 300 to 500 ml rarely being required.

Procaine Amide (Pronestyl). This drug has essentially the same effect as quinidine, the indications for its use are the same, and there have been no well-controlled studies that clearly demonstrate the superiority of one over the other. It is convenient to have an alternative, if the patient happens to be hypersensitive to the other. Orally, procaine amide 0.25 to 1.0 Gm is given two to four times daily, and the same doses may be administered intramuscularly. Its most important use is in the treatment of *ventricular tachycardia* for it can be given intravenously with reasonable safety. Since hypotension may be present as a result of the ventricular tachycardia or the myocardial infarction or may be caused by the procaine amide, a flask containing levaterenol and a flask containing procaine amide (2.0 Gm diluted in 250 ml 5 per cent glucose) are joined by a Y tube as described in the discussion of the pressor amines. If hypotension is already present, levaterenol should be allowed to flow in until the desired blood pressure level is attained. If this does not terminate the tachycardia, procaine amide is then given at a rate of 1.0 Gm in 1 hr. Blood pressure observations are made from the other arm and very frequent electrocardiographic tracings taken. If the blood pressure falls appreciably, procaine amide is stopped temporarily and levaterenol given. If the ectopic rhythm is converted to a normal sinus rhythm during the flow of the procaine amide solution, as is usually the case, the infusion is discontinued. If conversion does not take place, the second gram in the remaining 125 ml solution is given after waiting 1 hr. If the ectopic rhythm is abolished, the patient is then given a maintenance dose of procaine amide or quinidine for about 4 weeks.

Potassium. The chief use of potassium is in the treatment of *arrhythmias caused by digitalis intoxication*, and especially where there is reason to believe that potassium depletion has occurred, as through vigorous diuretic therapy, vomiting, or diarrhea. When the patient does not appear to be critically ill, 1.0 Gm of a potassium salt (4 ml of 25 per cent solution of potassium chloride or a similar amount of elixir potassium triplex) well diluted is given orally every hour for five doses. If the patient's condition demands more aggressive action, 5.0 Gm of the potassium salt is given orally and if, at the end of 2 hr, the manifestations of toxicity have not appeared, an additional 2.5 Gm dose is given. If the patient appears to be critically ill, 40 mEq potassium dissolved in 500 ml 5 per cent glucose in water is administered over a period of 2 hr. A similar amount may be repeated if necessary. Electrocardiographic control is essential when

large amounts of potassium are given, especially during the period of intravenous administration.

Other Drugs. Corticosteroids, such as dexamethasone 0.75 mg or prednisone 5 mg (4 to 8 tablets per day of either), are frequently effective in *heart block with Stokes-Adams attacks*. Chloroquine 0.25 Gm four times a day, diphenylhydantoin sodium (Dilantin) 250 mg in 1 liter glucose in water given intravenously, reserpine and other tranquilizers, 10 ml of 20 per cent magnesium sulfate given intravenously—all these have been reported as having been successful in serious arrhythmias, such as *ventricular tachycardia*, when procaine amide or quinidine have been ineffective. More studies with each of these are required before we can judge of their place in the management of the various arrhythmias.

Sinus Arrhythmia. This type of irregularity is observed in most healthy young persons at rest, and consists of a quickening of the heart during inspiration and slowing during expiration. It tends to be intensified by deep breathing and to disappear when the breath is held or when the heart rate is increased by exercise or fever. This arrhythmia has no significance.

Premature Beats. These may arise in the atrium, the junctional tissues, or much more frequently, in the ventricle. They are relatively more frequent in patients with structural cardiac disease than in healthy persons, but they are so common in the healthy that their presence has no diagnostic significance unless they appear only or increase in frequency markedly after exercise; or when numerous premature beats occur, about 8 to 12 or more per minute. In the latter case, atrial extrasystoles may be a forerunner of atrial fibrillation, or ventricular premature beats, particularly when of variable form, may indicate a more or less serious disturbance of ventricular function. Occurring in the absence of organic heart disease, premature beats may be due to excessive use of tobacco, coffee, tea, and occasionally alcohol or to reflexes from the gastrointestinal tract; often they are caused by emotional stress, or no definite factor can be ascertained. The premature beat is usually recognized with ease because it consists of a contraction appearing before the next beat would ordinarily occur and is usually followed by a pause longer than the usual interval. The patient may or may not be conscious of the premature beat (p. 90). When the extrasystoles are frequent, there may be confusion with atrial fibrillation, an error that can be avoided by noting that the rhythm becomes regular when the heart is accelerated by exercise.

There is still uncertainty whether the premature beat is caused by an irritable focus or by reentry, the available evidence favoring the former view.

The *bigeminal rhythm*, a state in which every alternate beat is premature, is usually the result of

digitalis overdosage and disappears within a few days after the drug has been withheld. It should not be confused with *pulsus alternans* or with the *paradoxical pulse* (p 1468); in the latter two, the rhythm remains regular. Bigeminy not due to digitalis is usually, though not always, associated with structural heart disease.

The treatment of premature beats depends on the circumstances. When they occur only occasionally, and evidence of cardiac disease is lacking, no treatment is necessary. When there is reason to believe that tobacco or coffee is responsible, its use should be discontinued or curtailed. In excitable patients, extrasystoles may disappear following the administration of a mild sedative: barbiturates, reserpine, or other tranquilizers. In fully digitalized patients, premature beats, if caused by the digitalis, will disappear if the drug is withdrawn, or, if the irregularity occurs after the ingestion of a high carbohydrate meal, it will be abolished by the administration of potassium. It should also be mentioned that the occurrence of extrasystoles not caused by digitalis does not constitute a contraindication to the use of digitalis if the patient suffers from congestive failure. Often with the restoration of myocardial function, the irregularity will disappear. Quinidine, procaine amide, and digitalis are all effective in the treatment of extrasystoles, the relative efficacy of each drug varying in different patients.

While premature beats may ordinarily be considered a benign form of irregularity, the occurrence of numerous such beats may diminish the efficiency of the heart whose reserve is already impaired. Moreover, the appearance of ventricular extrasystoles following an acute myocardial infarction should not be viewed with complacency, since they may then herald the onset of ventricular tachycardia; or an isolated ventricular beat, occurring in the "vulnerable" period, at the end of the previous systole, may initiate ventricular fibrillation and sudden death. It is for this reason that some believe that quinidine, in the form of the long-acting gluconate, 0.3 Gm two times daily should be administered in all patients with acute ischemic heart disease, although this policy is not accepted by others.

Atrial Fibrillation. The effect of atrial fibrillation is to obliterate the effective contraction of the atria and to bombard the atrioventricular node and the ventricles with a very rapid and irregular series of stimuli. Many of these impulses are blocked at the AV node, but many are passed through, so that the ventricular contractions in the untreated patient are usually rapid and completely irregular.

The untoward effects of atrial fibrillation depend on the rapidity of the ventricular rate and the extent of the pulse deficit (i.e., on the proportion of ineffective and wasted ventricular beats), on the

prior state of the affected heart, on the duration of the arrhythmia, and on the virtual paralysis of effective atrial contraction. Cardiac output may be diminished as a result of the reduction of total diastolic filling time and also because coordinated atrial contraction may be essential for adequate ventricular filling: the net result may be myocardial failure. Stagnation of blood in the essentially paralyzed atria tends to predispose to the development of thrombi and embolism in both pulmonary and systemic circulations. Finally, the cardiac irregularity, if uncontrolled, gives rise to an unpleasant consciousness of palpitation.

When the rate is rapid, 120 or more, the diagnosis is readily made, because atrial fibrillation is the only common condition in which one observes the combination of a well-marked tachycardia with a gross irregularity. When the rate is normal or only slightly increased, as in digitalized patients, the diagnosis is less apparent. The distinction from numerous extrasystoles can be made by noting that it is only in atrial fibrillation that abnormally long pauses occur in groups of two or more. Moreover, exercise tends to abolish the extrasystolic arrhythmia, whereas it exaggerates the irregularity of atrial fibrillation. More difficult, and frequently impossible, is the differentiation of fibrillation from atrial flutter with varying block, and from a shifting pacemaker associated with multiple atrial ectopic beats.

Atrial fibrillation may be paroxysmal or persistent. Occasionally the paroxysmal form occurs in healthy persons in whom no evidence of structural cardiac disease can be found. It is also encountered in individuals who, otherwise normal, suffer from acute infections such as pneumonia, or in patients with rheumatic heart disease or acute myocardial infarction. Rarely, paroxysmal atrial fibrillation may be the consequence of anesthesia; potassium deficiency, digitalis intoxication, or other forms of poisoning. Most frequently, however, paroxysmal atrial fibrillation is seen in thyrotoxicosis, mitral stenosis, or in senile heart disease, usually associated with coronary disease. In the latter group, the paroxysmal attacks frequently occur before the arrhythmia is permanently established. The paroxysmal bouts may last for a few seconds to a few days, and as is true in all types of paroxysmal rapid heart action, the onset and offset are sudden. Unless the patient happens to be observed in the midst of an attack, the nature of the episode will depend on the observation of the patient that the heart action is highly irregular during the attack.

The permanent form of atrial fibrillation is confined almost exclusively to patients with senile heart disease, mitral stenosis, or thyrotoxicosis. In elderly patients the usual signs of thyrotoxicosis may be absent and the arrhythmia may be the only feature

suggesting the possibility of thyroid disease. Rarely, chronic atrial fibrillation may be the sole cause of congestive failure that persists despite full digitalization, and in such instances reversion to normal rhythm is a curative procedure. When the ventricular rate fails to slow in the usual fashion after full doses of digitalis, the presence of thyrotoxicosis, a recent silent coronary occlusion, multiple pulmonary infarcts, or acute rheumatic carditis should be suspected. The onset of the ectopic rhythm in a person who has received therapeutic doses of digitalis and of diuretic drugs, such as mercurials or chlorothiazide, may be a manifestation of potassium deficiency and an indication for potassium therapy.

In a person with atrial fibrillation, one faces the choice between two plans of therapy: that of attempting to control the ventricular rate with digitalis, the rhythm remaining irregular; and that of abolishing the arrhythmia by quinidine or other antiarrhythmic drugs. In patients with mitral stenosis, or with marked cardiac enlargement with failure, quinidine is rarely successful in permanently restoring a normal sinus rhythm, and in these patients, the drug appears to be especially hazardous. In other patients with chronic atrial fibrillation, a normal rhythm can be restored if one administers large enough doses of quinidine, often bordering on toxic ranges, but usually the normal sinus rhythm can be maintained only by permanent maintenance doses of quinidine and even so but for a variable period of time before the arrhythmia reasserts itself. In general, patients with chronic atrial fibrillation can be well controlled with digitalis, and little is gained by the conversion of the arrhythmia to a normal sinus mechanism. Hence, quinidine is likely to be of greatest value in patients with fibrillation of recent development who are known to have had no evidences of congestive failure prior to the onset of the arrhythmia. It should also be given when the ventricular rate is not well controlled by digitalis; and it may be given in intractable failure provided one recognizes the risks inherent in quinidine therapy under these circumstances. In all cases of atrial fibrillation, therapeutic doses of digitalis should be administered before quinidine is given. Following acute myocardial infarction with atrial fibrillation, it is particularly important that one's first and most important objective be the slowing of the ventricular rate with digitalis. For the treatment of paroxysmal atrial fibrillation, a rapid-acting digitalis such as lanatoside C is preferable, while for the control of the established fibrillation, one of the slower-acting digitalis preparations should be used (p. 1396). The details of quinidine therapy are described above (p. 1396).

One point needs emphasis: although there are many instances of transient atrial fibrillation in which the administration of digitalis is followed by

the disappearance of the arrhythmia, when atrial fibrillation is of long duration, digitalis rarely abolishes the ectopic rhythm. Under these latter circumstances, the ventricular rate slows and becomes less obviously irregular unless a complete AV block and a regular idioventricular rhythm develops; but electrocardiographic tracings reveal that the atria continue to fibrillate.

Thromboembolism is common in patients with atrial fibrillation, particularly the chronic form, and is especially frequent in patients who also have mitral stenosis, being responsible for about 20 per cent of the deaths in the latter. To prevent such catastrophes, long-term anticoagulant therapy has been advocated, especially important in patients who have already experienced one or more episodes of embolism.

Regular Tachycardias. Given a patient with well-marked increase in the heart rate, or with a history of such attacks, the first decision to be made is whether one is dealing with sinus tachycardia or with one of the ectopic tachycardias. The latter group will usually respond to therapy aimed directly at the heart, while in the case of sinus tachycardia, the treatment of the rapid rate depends on the management of the underlying condition. If one can obtain a reliable history of sudden onset and offset, one knows immediately that the attack represents an ectopic tachycardia of some type. However, the patient is often unable to state whether the onset is absolutely sudden, and even when a paroxysmal tachycardia has actually taken place, still less often is he certain that the ending was abrupt. When the rate is less than 140 per minute, the chances are strong that one is dealing with sinus tachycardia, but one must bear in mind the occasional patient with atrial flutter with a ventricular rate below 140, and above all, that form of serious digitalis intoxication known as paroxysmal tachycardia with AV block (p. 1400). Rates of 170 or more per minute are almost invariably the result of ectopic rhythms, and the difficulty comes chiefly in the group of patients with heart rates between 140 and 170. The response to carotid sinus pressure is important in the differentiation; often, the definitive diagnosis is made only by electrocardiography.

Extreme Sinus Tachycardia. The chief causes of extreme sinus tachycardia are marked elevation of body temperature, severe thyrotoxicosis, any condition that produces profound circulatory collapse, and occasionally an anxiety attack or acute myocardial injury due to infection or infarction. In most instances, however, sinus tachycardia of severe degree is due to extracardiac causes. Sinus tachycardia usually responds little or not at all to carotid sinus pressure, in the latter case resembling ventricular tachycardia. If there is a slight response,

neither the slowing nor subsequent acceleration occurs with the abruptness observed in patients with atrial flutter or paroxysmal tachycardia with AV block. In the absence of marked hyperthermia, severe thyrotoxicosis, or anxiety state, a patient with outspoken sinus tachycardia will usually display manifestations of forward failure (p. 101). Digitalis or other cardiac therapy has no value in normal sinus tachycardia unless there are manifestations of congestive failure. The problem is discovering the basic cause and correcting it.

Paroxysmal Atrial Tachycardia. This is the most common of the ectopic tachycardias aside from atrial fibrillation. It is generally attributed to rapid discharges from an irritable focus. Usually it appears first in youth, and attacks may recur throughout life. The majority of patients with this disorder display no evidence of any other cardiac abnormality, and in the absence of structural disease, atrial tachycardia should be considered a benign affection except under circumstances described above (p. 1395). They may, however, produce great anxiety on the part of the patient and his family. When a patient is seen during an attack, the heart is found to be perfectly regular and the rate is 160 to 170 or more. Procedures such as carotid sinus pressure or other types of vagal stimulation will have no effect or will terminate the attack abruptly. Atrial tachycardia may be accompanied by such an aberration of the QRS complex that an erroneous diagnosis of ventricular tachycardia may be made and sometimes the differentiation may be impossible.

The causes of atrial tachycardia are not known since most patients exhibit no signs of organic disease. Prognosis is excellent unless the attack brings on congestive failure or myocardial ischemia. The keystone of therapy is reassurance coupled with attempts to prevent the seizures and to terminate the disorder when it occurs. For many patients digitalis is the most effective drug for the prevention of the attacks; in others, quinidine is more useful. Certain patients notice that the attacks are regularly precipitated by certain trigger factors, such as anxiety or digestive disturbances, and avoidance of these will have a salutary effect. In many, the attacks occur at such long intervals that the patient himself will prefer to treat the disorder only when it transpires rather than to take a drug indefinitely to prevent the ectopic rhythm.

For the treatment of paroxysmal atrial tachycardia, the patient should assume the recumbent position and be given a sedative, such as sodium pentobarbital or secobarbital, 0.2 Gm given intramuscularly. If significant hypotension is present, 90 mm systolic or less, slightly higher if the patient has previously been hypertensive, elevation of the blood pressure by phenylephrine to not more than 100 mm systolic may suffice to restore a normal rhythm

or to make the heart more responsive to other measures (p. 1396). The carotid sinuses should be massaged for about 15 to 20 sec, each one separately, while listening to the heart, discontinuing the massage if the rate slows abruptly. If the ectopic rhythm persists, lanatoside C, 0.8 to 1.2 mg, should be given intramuscularly or very slowly intravenously, provided, of course, that the patient has not received digitalis during the preceding 2 weeks. The digitalis acts as a vagal stimulant. If after 1 hr the tachycardia continues, carotid sinus pressure should again be attempted, and if this fails, neostigmine (Prostigmine) 0.5 to 1.0 mg, a cholinesterase antagonist, may be administered intramuscularly, followed again by carotid sinus massage. If all these measures fail, morphine sulfate 10 to 15 mg subcutaneously is given, and during the ensuing sleep the attack will usually cease.

Almost invariably one or more of these procedures will be effective and methacholine (Mecholyl), a very powerful vagal stimulant and likely to produce alarming reactions, is practically never required. Quinidine may be given by mouth or parenterally, but it is not often needed.

The treatment outlined above refers to the measures taken by the physician. Often, however, the patient has previously learned how to terminate the attack by utilizing carotid sinus pressure, or by inducing gagging and vomiting, or by the Valsalva maneuver (attempting to expire against a closed glottis). Naturally, these simple methods can also be employed by the physician before carotid sinus massage or drug therapy is instituted.

Paroxysmal Atrial Tachycardia with Block. It is primarily through the investigations of Lown and his associates that the importance and significance of this disorder have been recognized. The arrhythmia has certain characteristics of flutter in that the responses to vagal stimulation are similar; in other respects, it resembles atrial tachycardia in that the atrial rate usually lies between 150 and 250. It is generally considered to be a variant of flutter, and the exact mechanism is not known. Digitalis intoxication is the usual cause, and on this account, this ectopic rhythm requires separate discussion because the treatment is altogether different from that of atrial tachycardia or flutter. Sensitivity to digitalis increases with the severity of heart failure, age, and particularly with potassium depletion, usually resulting from excessive diuretic therapy or vomiting or diarrhea, in a patient on a low-sodium diet. Thus, under these circumstances, serious digitalis intoxication may ensue with doses that would ordinarily be considered physiologic.

Paroxysmal atrial tachycardia with block should be sought for in any digitalized patient who displays other symptoms of intoxication such as nausea and vomiting, or who has received vigorous diuretic

treatment or who may otherwise have lost potassium as a result of vomiting or diarrhea, or whose heart rate increases after having received full doses of digitalis. The diagnosis is established by obtaining an electrocardiographic tracing displaying an atrial rate of 150 to 250, an isoelectric line between P waves in all leads, and AV block more pronounced than mere prolongation of the P-R interval.

The earliest stage is an alteration in the form of the P wave and an increase in the atrial rate, usually with a 1:1 ventricular response. Thus, the rate may increase to 120 to 140 and still resemble a normal sinus rhythm, the impaired AV conduction inapparent except when carotid sinus pressure is applied. At higher atrial rates, a 2:1 block usually appears. *The danger of this abnormal rhythm comes from the fact that it is a manifestation of serious digitalis poisoning, is likely to be confused with a sinus tachycardia or flutter, and because of the presence of congestive failure, digitalis may be pushed even more vigorously.* The proper treatment is prompt cessation of digitalis and of diuretic drugs and the administration of potassium by mouth or parenterally (p. 1397), depending on the urgency. *The serum potassium level must not be relied on as a criterion of diagnosis; most patients with this form of disturbed heart action have little or no diminution in the level of serum potassium.*

In about 20 per cent of patients, the arrhythmia is unrelated to digitalis intoxication and potassium depletion. Procaine amide is then employed. If there is doubt about the role of potassium depletion and there is no uremia that could cause a hyperkalemia, and there is no electrocardiographic evidence of excessive serum potassium, potassium therapy may be tried. If this is ineffective, procaine amide should be given.

Atrial Flutter. This arrhythmia is much less common than fibrillation, but it is very closely allied and the mechanism must be similar. As a rule, the atria beat at a rate of approximately 300 and a 2:1, 3:1, 4:1 AV block exists, the corresponding ventricular rates being 150, 100, or 75. When the block is constant and of high degree, the condition will usually not be suspected; but if it is suspected, its presence can be confirmed by the fact that exercise increases the rate suddenly rather than gradually, and in the postexercise period slowing occurs suddenly, not gradually. This behavior arises from the fact that exercise and flutter have no influence on the atrial rate, but the decrease in vagal tone reduces the degree of block, a 4:1 giving way to a 2:1 block, for example, and the acceleration occurs within one beat; the reverse takes place as vagal tone is restored in the postexercise period. Usually, a 2:1 block is present when the patient is seen and the ventricular rate lies between 140 to 160. This fact alone should make one suspect the

presence of flutter, because other types of ectopic tachycardia are likely to be associated with faster rates. Carotid sinus pressure slows the ventricular rate in flutter by increasing vagal tone and hence the degree of AV block. The slowing is maintained only for the brief period of pressure, and both the slowing and quickening occur instantly rather than gradually, as would be the case with sinus tachycardia if there were any response at all. Occasionally, the block is so variable that the ventricular irregularity is virtually identical with that observed in fibrillation. However, after exercise, the irregularity of flutter tends to disappear whereas in fibrillation it is enhanced.

Careful auscultation will frequently reveal an appreciable difference in the intensity of the first sound in flutter, due to slight variations in timing of the ventricular contraction in relation to the preceding atrial contraction (p. 89). This variation in the loudness of the first sound is never present in sinus tachycardia or paroxysmal atrial tachycardia, but it occurs frequently in ventricular tachycardia and thus serves to limit the diagnostic possibilities when a tachycardia is first encountered.

Flutter is caused by essentially the same conditions that cause fibrillation, has essentially the same prognosis, and is treated in a somewhat similar manner. The usual method of treatment is to give digitalis, which slows the ventricular rate by increasing the degree of AV block, and commonly converts flutter to fibrillation. When the drug is withdrawn, these patients will frequently revert spontaneously to normal rhythm; if this does not occur, quinidine may be employed. If the abnormal atrial rhythm cannot be abolished, digitalis is given in doses sufficient to maintain the ventricular rate at a relatively normal level.

Quinidine sometimes converts atrial fibrillation to flutter and the flutter may persist, the atrial rate decreasing from about 300 to 200. Under these circumstances, the ventricular rate may suddenly increase, the previous 2:1 ratio being replaced by a 1:1 response. Quinidine should be discontinued and digitalis administered even though fibrillation will probably be reestablished.

Paroxysmal Ventricular Tachycardia. This is much less frequent and far more serious than paroxysmal atrial tachycardia. The commonest cause is coronary disease, and this arrhythmia frequently occurs within a few days following the development of an acute myocardial infarction. Less commonly, it is induced by digitalis or quinidine intoxication, and very rarely the arrhythmia appears spontaneously in healthy persons without any evidence of cardiac disease. The diagnosis should be suspected when the following clinical features are observed: (1) The patient has evidence of coronary disease or has been receiving digitalis or quinidine in large

doses (2) As a rule, there is no history of numerous previous attacks. (3) During the attack, the ventricular rate is usually between 160 and 210, and although it is essentially regular, there are often slight variations in the regularity of the rhythm and in the intensity of the first sound from beat to beat because the relationship between the atrial and ventricular contractions is somewhat variable. (4) Carotid sinus stimulation has no effect on the rate.

Although these clues are very important, the clinical impression should be confirmed by an electrocardiogram, but even here the interpretation may be rendered difficult because atrial tachycardia may be associated with ventricular conduction defects (aberrant QRS complexes) which cause the tracing to resemble that of ventricular tachycardia. In other words, the electrocardiographic diagnosis cannot be made with certainty on the sole basis of the abnormal complexes. In addition, it is necessary that the P waves be shown to occur at a rate independent of the ventricular rate, or that there be demonstrated, in the intervals between attacks, ventricular premature beats identical in form with the complexes seen during the paroxysm.

Since it is but one step removed from the almost invariably fatal ventricular fibrillation, ventricular tachycardia is the most serious of the ectopic tachycardias. If the attack occurs during a bout of acute myocardial infarction, quinidine or procaine amide (p. 1397) may be effective in terminating it, but one should not adopt an attitude of complacency, for there is a strong probability that another episode will soon recur. Hence, a maintenance dose of the successful drug should be continued until the healing of the infarct is complete.

When heart failure occurs in an undigitalized patient with ventricular tachycardia, digitalis should be administered since the drug is not especially hazardous in such patients, as was formerly believed.

Some patients with ventricular tachycardia who are receiving large doses of quinidine or of procaine amide fail to revert to the normal mechanism but do exhibit marked slowing—to 120 per minute or less—of the ectopic rhythm. Under these circumstances the administration of large doses of atropine (up to 2 mg intravenously) may increase the atrial rate to a level above that of the ectopic rhythm and so permit the sinoatrial node to resume its normal role as pacemaker and thus restore the normal sinus mechanism.

When all these measures fail and the patient's condition remains critical, external countershock (250 to 400 volts) may be employed. This procedure requires general anesthesia.

Ventricular Fibrillation. This arrhythmia may occur in very brief bursts, lasting for a few seconds,

then subsiding spontaneously, following which the rhythm previously present is resumed. These episodes are responsible for some of the Stokes-Adams attacks that characterize high-grade AV block. Usually, however, ventricular fibrillation is synonymous with practically instantaneous death, since effective ventricular contraction and circulation cease. Aside from AV block, ischemic heart disease is the most common cause of the arrhythmia, particularly during attacks of acute myocardial infarction. There had been no treatment for this calamitous disorder until the introduction of externally applied countershock. Needless to say, this form of therapy must be applied promptly, for cessation of the circulation beyond 2 to 4 min leads to irreversible damage in the brain and heart. This means that a candidate for the arrhythmia, whether he is suffering an acute myocardial infarction or has sustained a series of Stokes-Adams attacks, must be under constant observation, and there must be constant readiness to apply countershock. This incessant watch may be required for weeks, until the patient has been free of attacks for at least a few weeks. In the absence of this special equipment, vigorous pounding of the precordium, coupled with artificial respiration, preferably mouth-to-mouth, may be attempted. If the heartbeat does not return immediately, the procedure of closed-chest cardiac massage should be employed. This involves manual rhythmic compression of the sternum once per second, plus mouth-to-mouth respiration. Thus it may be possible to sustain life during the crucial time required to secure and apply the apparatus needed for countershock.

Wolff-Parkinson-White Syndrome (Anomalous Atrioventricular Excitation). This is a congenital disorder characterized by the presence of normal P waves, a P-R interval of 0.1 sec or less, an increased QRS interval, a slur on the initial phase of the QRS complex (delta wave), and a pronounced tendency for the occurrence of paroxysmal tachycardia: either atrial tachycardia or atrial flutter or fibrillation. It is thought by some that the entire picture is based on the presence of an accessory neuromuscular tract (the bundle of Kent) connecting the atria with the ventricles over which impulses bring about premature activation of a portion of the ventricular musculature. There is other evidence that the disorder is caused by accelerated conduction through some of the fibers in the AV node or bundle.

The electrocardiogram shifts between the abnormal (W-P-W type) and the "normal," although this latter may now reveal abnormalities that have been masked by the W-P-W form. Since the latter displays a Q in leads II, III, and F, it is not infrequently mistaken for the tracing of a myocardial infarction, especially when the patient is in the

midst of an attack of paroxysmal tachycardia, which occurs in about 75 per cent of the patients with this anomaly. The shift to the anomalous conduction can be induced by vagal stimulation as by carotid sinus pressure or by digitalis given intravenously. The normal type of conduction can be brought on by vagal inhibition as by atropine or exercise, also by quinidine and procaine amide.

The condition should be suspected in any person subject to paroxysms of tachycardia, particularly when they have occurred from youth. The diagnosis is established by careful scrutiny of the electrocardiographic tracings for the criteria enumerated above. Since digitalis appears to be less effective than usual in the treatment of the paroxysms of rapid heart action, quinidine or procaine amide should be employed for such attacks. A few instances of sudden death during an attack have been reported. Hence, with a history of frequent bouts of paroxysmal tachycardia, maintenance doses of either quinidine or procaine amide should be given indefinitely.

Sinus Bradycardia. This is a condition in which excitation of the heart proceeds in the normal fashion, although the sinoatrial pacemaker discharges at the unusually slow rate of about 40 to 50. It is occasionally seen in normal persons, particularly trained athletes. It may also be encountered in patients with increased intracranial pressure, in convalescence after febrile illnesses, in obstructive jaundice and myxedema. Practically never does the slow heart alone cause symptoms, for cardiac output is maintained at a normal level through a corresponding increase in stroke volume. Differentiation from complete AV block is readily made by electrocardiogram and also by the quickening of the heart rate with atropine and exercise, and the failure of these measures to bring about an appreciable increase in ventricular rate in complete AV block.

Heart Block. This term refers to a condition in which the wave of excitation from the atria is delayed or blocked at the junctional tissues (AV node and common bundle). The P-R interval represents the time required for the impulse to traverse the AV node and bundle, and 0.20 to 0.21 sec is generally accepted as the upper limit of normal. When the P-R interval exceeds this period of time and all the atrial beats are followed by ventricular beats, the state is called *first degree block*. A more advanced disturbance in the conduction system, *second degree block*, is present when from time to time the atrial impulses are incapable of penetrating the conduction system and of exciting the ventricles. *Third degree or complete heart block* describes the condition in which the conduction system is so altered that no atrial impulses reach the ventricles, and the atria and ventricles maintain separate and independent rhythms.

First Degree Block. This may be due to increased vagal tone in a healthy, normal person. We have seen an Olympic champion whose P-R interval is regularly 0.26 to 0.28 sec. Prolongation may be caused by impairment of the conduction system as a result of digitalis or any of the inflammatory, toxic, degenerative, or vascular processes that may affect the heart. Prolongation of the P-R interval, as may occur in rheumatic fever, may be suspected when the intensity of the first heart sound suddenly declines in intensity without any other change in the clinical picture and without evidence of fluid in the pericardium, or when a presystolic murmur becomes middiastolic in the absence of atrial fibrillation.

In the absence of any other criteria to indict the heart, this one electrocardiographic deviation from an arbitrary norm should not be construed as evidence of organic heart disease, and it requires no treatment.

Second Degree or Partial Heart Block. The careful and extensive studies of Gilchrist have illuminated important aspects of partial heart block that have not previously been widely appreciated. We draw on his observations freely in this discussion. Second degree block may be divided into two groups. In the benign form, type I, the P-R interval increases progressively until finally an atrial beat is completely blocked, the corresponding ventricular beat dropping out (Wenckebach pause). The P-R interval after the pause shortens to within the normal range but each successive one lengthens, and the cycle is repeated. The dropped beat may occur after six to eight conducted beats, or it may take place after every second atrial impulse, thus giving rise to a 2:1 AV block and becoming indistinguishable at first glance from the more serious 2:1 block to be described below. However, the differentiation can be readily made by inhibition of vagal tone, as by intravenous injection of atropine (1 to 2 mg) or exercise. In the benign type I, the block diminishes or disappears with such a procedure, whereas it increases with type II partial block and may promptly develop into a complete, though temporary, AV block. Type I second degree block is usually due to increased vagal tone, occurring spontaneously or after carotid sinus pressure or following digitalis therapy. It is almost always a transitory phenomenon and requires no treatment.

Type II, a far more serious disorder, appears as a 2:1, 3:1, or 4:1 block, the P-R interval being either normal or increased, but always fixed and unvarying. This form of heart block may be caused acutely by a posterior myocardial infarction or by diphtheria, usually a transient block with the former, almost always with the latter. It may also result from coronary sclerosis in the absence of an acute episode of infarction, calcification of the mi-

tral annulus, extension of the lesion of aortic stenosis into the septum, any of the diffuse disorders of the myocardium (p. 1464), or congenital heart disease, usually a patent ventricular septum.

Syncope attacks are common in type II block, and they display the characteristics of all such syncope attacks as are due to a sudden cessation of circulation (p. 305). The attacks occur suddenly and without warning and in both the upright and recumbent postures, in contrast to the premonitory lightheadedness, faintness, "blacking out" that always precede the simple vasodepressor syncope which always develops in the upright position and is relieved by the recumbent posture. If patients with type II 2:1 block, for example, are carefully observed during or shortly after the lapse of consciousness, ventricular standstill or fibrillation will be recorded during the syncopal period, followed by complete block in the early recovery state, a 2:1 block being restored after a few hours or days. When a person with a slow heart rate or with an electrocardiographic tracing of partial block develops a syncope attack with the characteristics described above, the diagnosis should be simple. However, in a number of patients, syncope attacks may appear at relatively long intervals over a number of years, during which time the electrocardiogram may be perfectly normal and the P-R interval well within the normal range. Nevertheless, intravenous atropine in such persons will usually unmask a concealed block. *The important lesson to be drawn is that, when a middle-aged or elderly person gives a history of syncope attacks that develop without warning, one should suspect a Stokes-Adams attack even if the electrocardiogram at the time of the examination is normal in all respects. Eventually, most of the persons with type II block, whether of the overt or concealed form, will develop complete block, if prior to this eventuality, they have not succumbed in a Stokes-Adams attack or to some other disease. One condition, less serious, that may cause identical syncope attacks, is a hypersensitive carotid sinus that is responsible for fainting attacks of the cardioinhibitory type.*

Complete or Third Degree Block. This condition is caused by any of the disorders responsible for type II partial block. Occasionally, one encounters an otherwise normal person with congenital block, and rarely a patient with persistent complete block will be found at autopsy to display no demonstrable microscopic lesion in the conduction system. A transitory form, lasting a few seconds, may follow carotid sinus pressure, and it may also be a consequence of digitalis intoxication, disappearing a week or two after the drug is withdrawn. The ventricular rate is 45 or less, although following an acute posterior infarction or digitalis intoxication, the rate may be as rapid as 65. The rhythm is regular, and

the rate increases slightly after exercise. Paradoxically, the rate may increase after atropine. The intensity of the first heart sound varies from beat to beat, sometimes being almost inaudible and at other times so loud as to merit the term *bruit de canon* (p. 89). Faint atrial contractions can also be heard, and if atrial contraction occurs during an early ventricular filling period, a short blowing mitral diastolic murmur may be heard and recorded (Ryland murmur).

The prognosis of first and second degree, type I, block is favorable. The outlook for high grades of block (type II, partial or complete AV block) is always uncertain since the patient is constantly subject to the risk of Stokes-Adams attacks, any of which may be fatal. When such attacks occur frequently in patients with complete block and are uncontrolled, death usually occurs within a year. During this period the patient who is having numerous and prolonged attacks seems, like Castor and Pollux, to alternate between the realm of the living and the kingdom of the dead. In acute myocardial infarction, the presence of high-grade block doubles the risk during the first 2 to 3 weeks.

Treatment of Heart Block. The important problem is the management of the Stokes-Adams attacks. The most generally effective drugs are the sympathomimetic agents, such as isoproterenol, epinephrine (aqueous or suspended in oil), and ephedrine. In acute myocardial infarction they may also be employed but all these drugs, including isoproterenol, the one most favored, increase myocardial metabolism and, hence, tend to cause hypoxia and occasionally prolonged anginal attacks. Should these occur, the drugs should be discontinued promptly. Corticotropin and corticosteroids sometimes are efficacious when the sympathomimetic drugs are not helpful or cannot be continued; the mechanism of their beneficial effect is not certain. Because potassium depletion accelerates conduction, chlorothiazide, 500 to 750 mg combined with sodium bicarbonate 10 Gm given throughout the day, has been found to exert a favorable effect in partial heart block. In life-threatening situations where syncope attacks are frequent and uncontrolled, the application of the external pacemakers under constant observation may be used for ventricular standstill and external countershock for ventricular fibrillation, and these measures may tide the patient over a very stormy period. During the minutes required to initiate these procedures, life may be sustained by the method of closed-chest cardiac massage, as discussed on p. 1402. For congestive failure in conjunction with complete block, digitalis may be used without reservation. With partial block, digitalis therapy may either improve or worsen the degree of block. Hence the drug should be withheld unless congestive failure fails

to respond to other measures. *Under no circumstances should quinidine or procaine amide ever be used in the presence of high-grade block, regardless of what other indications may exist, since in these patients the fibrillatory action of these drugs predominates over the antibrillatory effect.*

When, despite drug therapy, syncopal attacks continue at frequent intervals, an internal pacemaker may be inserted surgically.

Bundle Branch Block. These disorders, which are not arrhythmias in the strictest sense, may be conveniently mentioned at this point. When the duration of the QRS complex is 0.13 sec or more, and when the main deflection is positive in leads I and V_6 and negative in leads III and V_1 , left bundle branch block is said to be present. Similar prolongation but with the opposite directional deflections in the leads mentioned, is characteristic of right bundle branch block. Lesser degrees of QRS lengthening with an RST pattern are often designated as incomplete left or right bundle branch block. In some instances there may be marked prolongation of the ventricular complex without the above-mentioned characteristic reciprocal changes in the opposite leads. These are usually considered interventricular block.

These several disorders are all related to delayed spread of ventricular excitation. The commonest causes are coronary disease, inflammatory or infiltrative disease of the myocardium, and marked univentricular hypertrophy, producing delay in the spread of the impulse through the thickened chamber.

None of the rather numerous physical signs which have been attributed to bundle branch block are wholly reliable. The electrocardiogram remains the only consistently accurate method of diagnosis.

These disturbances of conduction are usually encountered in persons with advanced myocardial disease or severe pressure loads but may be seen in association with volume loads, atrial septal defect being the classic example. It is probable that the abnormal sequence of contraction consequent to the disordered excitation impairs further the effectiveness of ventricular systole. In a patient with heart failure, marked prolongation of the QRS adds to the gravity of the prognosis. However, when right bundle branch block is encountered in an asymptomatic person under the age of 40 who lacks all other objective evidence of cardiac disease, the outlook is excellent. In asymptomatic patients of any age with left bundle branch block, and in those with the right bundle disorder who are older than 40, the prognosis is less certain because there is always the possibility that the conduction disorder may be the sole manifestation of

coronary disease. Even so, any activity which causes no symptoms should be permitted.

It is probable that contusion of the heart (steering-wheel injury, boxing, football, etc.) is a frequent cause of the benign varieties of bundle branch block. However, a history of injury is not always obtainable, and the cause of these benign instances often remains uncertain.

The treatment of bundle branch block is that of the associated disorder. No therapy except judicious reassurance is indicated for those persons who lack symptoms and present no objective abnormalities other than the prolonged intraventricular conduction. It should be repeated that one treats patients—not electrocardiograms.

T. R. Harrison and
William H. Resnik

Dyspnea and ischemic pain, which are the most important subjective manifestations of structural disease of the heart, have been discussed in earlier chapters (pp. 104 and 32). The objective signs fall into two general groups: those which are related to cardiac failure (Chap. 249) and which are found mainly in organs other than the heart, and those which are due to cardiac disease and which are detected by examination of the heart itself. It

is with the latter phenomena that this chapter is concerned. It should be emphasized that, while these objective signs of abnormality are almost invariably concomitants of heart disease in young persons, they are often absent in older patients, despite the presence of a serious disorder.

CARDIAC ENLARGEMENT

Increase in the size of the cardiac shadow due to pericardial effusion, which may exist in the absence of any enlargement of the heart itself, is considered in Chap. 236, Pericarditis. Aside from these effusions, the x-ray is of particular value in regard to dilatation but often fails to detect hypertrophy which, when marked, usually produces characteristic alterations in the electrocardiogram. A very slight degree of hypertrophy may elude recognition by all methods, including autopsy, but moderate degrees are frequently best found by palpation.

The normal apex tap is mainly due to recoil of the ventricles as ejection starts. Left ventricular hypertrophy usually produces an exaggerated apical thrust which is felt over a larger area and is longer sustained than the normal sharply localized brief tap. Similar changes may occur following apical infarction, and the differentiation between the two causes will depend on the associated findings. Less frequently, a striking but temporary exaggeration of the apex thrust appears during anginal attacks and vanishes as the pain subsides. The anginal and postinfarctional apical bulges are apparently caused by ballooning of feebly contracting ischemic areas, as the remaining healthy muscle undergoes vigorous contraction.

In the case of left ventricular enlargement the exaggerated thrust is probably due to one of two mechanisms, or a combination of them.

Since the base is normally thicker than the apex, an equal relative degree of hypertrophy will mean greater absolute thickening at the base and relative weakness of the apex. Thus the exaggerated apical thrusts due to ischemia and to hypertrophy are probably both related to an increase in the base/apex contractile ratio.

The mechanism of the exaggerated apex thrust seen with acute dilatation, in the absence of hypertrophy, is probably different. Here, the apex becomes rounded, with loss of the normal conical shape of the left ventricular cavity. Thus, since tension = pressure \times radius, the thinner apex is now subjected to the same tension as the thicker base, and this causes apical systolic ballooning. In the normal heart this does not occur because the smaller apical radius reduces the tension in that region.

Right ventricular hypertrophy usually produces

a diffuse precordial systolic lift which is more marked in the left parasternal than in the apical region. It is uncertain whether this is caused by exaggeration of the rightward-forward twist, which was first described by William Harvey, or by a change in shape of the right ventricle due to increased pull of the tricuspid ring toward the apex.

Elevated cardiac output, whether due to exercise, excitement, or such conditions as thyrotoxicosis or anemia, may also cause a diffuse precordial impulse. This is likewise often observed in patients with congestive heart failure, and in some persons with infarction of the interventricular septum, which apparently bulges toward the right ventricle when its contractile power is reduced. Similar but temporary changes may occur during anginal attacks. Patients with emphysema and low diaphragms often exhibit a pronounced systolic footward-forward thrust of the inferior cardiac border. This can be readily felt in the epigastrium, but must be distinguished from the forward pulsation of the abdominal aorta and the right subcostal systolic movement of the liver in patients with tricuspid insufficiency.

When hypertrophy is marked, the palpatory findings may be confusing because extreme hypertrophy of either ventricle may cause exaggeration of both the apical and parasternal motions. In this circumstance the electrocardiogram is more reliable. However, when hypertrophy is of moderate degree, simple palpation is usually more trustworthy than instrumental methods, provided the other conditions which have been cited can be excluded.

The x-ray sometimes supplies indirect information concerning hypertrophy by demonstrating valvular calcification. More commonly, it detects enlargement but does not distinguish between dilatation and hypertrophy. Since, in the absence of pericardial effusion, marked enlargement of the cardiac shadow is mainly due to dilatation, the x-ray is especially useful in detecting the latter process. It is also the most reliable method for recognition of atrial enlargement, although the electrocardiogram is sometimes valuable in this respect. Thus broad notched P waves and narrow tall P waves point toward hypertrophy of the left and right atria, respectively. Because the congenital lesions often produce bizarre and sometimes characteristic changes in the shape of the cardiac chambers or of the great vessels, the fluoroscopic and, especially, angiographic methods are particularly useful in these conditions (Chap. 252).

ALTERATIONS IN HEART SOUNDS

Improved methods for recording heart sounds have extended the information which can be obtained by auscultation. The following discussion,

which is based largely on the work of Leatham, deals mainly with such aspects of heart sounds and murmurs as can, with some practice, be elicited at the bedside. Phenomena which can be recorded but not readily heard will be mentioned only when they illustrate general principles.

The observer who desires to obtain maximal information from auscultation of the heart should keep two points constantly in mind: (1) In order to hear a faint sound or murmur it is necessary to listen specifically for it, i.e., to focus one's attention on that phase of the cycle during which the manifestation in question may be expected to occur. (2) The accurate timing (which is essential for correct interpretation) of a phenomenon necessarily involves relating it to known events. Frequently, the relationship to the first or second sound will suffice, but in many instances the clarification will come from simultaneous auscultation and inspection or palpation of the jugular pulse, the carotid upstroke, the apical thrust, or the precordial heave.

The low-pitched sounds and murmurs are best heard with gentle pressure, using the bell-shaped stethoscopic endpiece. However, high-pitched sounds, such as diastolic blows, are better heard with the diaphragm stethoscope, or with firm pressure if the bell is used. The tense skin then acts like a diaphragm and tends to transmit high-frequency vibrations.

The interventricular septum often inhibits the transmission of the left-sided phenomena to the anterior precordium. Hence the signs arising at the mitral valve are best heard at the apex, which is normally part of the left ventricle. Likewise, the second sound at the apex, as well as in the right second space, is mainly due to aortic closure. The tricuspid first sound is best heard in the fourth or fifth interspace just to the left of the sternum, while the pulmonic second is usually maximal in the second or third space. However, the blow of aortic insufficiency and the opening snap of mitral stenosis are exceptions; both these phenomena are often best heard in the tricuspid area.

There is still some dispute concerning the relative significance of valvular, muscular, vascular, and pericardial vibrations in the production of the heart sounds. In our opinion, the evidence indicates that abrupt change in tension of the valve cusps is the sole factor in the production of the audible components of the three normal sounds. Under abnormal conditions, the great vessels or the pericardium may produce sounds, but there is no convincing evidence that these ever arise in the myocardium.

Intensity. The chief factors which influence the intensity of the first sound are (1) the position of the valves at the onset of ventricular systole, which is usually determined by the length of time elapsing between atrial and ventricular contraction (p.

89); (2) the rate of rise of ventricular pressure; (3) the presence or absence of structural disease of the mitral valve; and (4) the amount of tissue, air, or fluid between the heart and the surface. Loudness of the first sound is favored by short conduction time, high cardiac output, mitral stenosis, and thinness. The reverse of these conditions tends to be associated with faintness of the first sound.

Aside from such extracardiac factors as obesity, emphysema, and effusions in the chest, the intensity and to some extent the quality of the second heart sound may be influenced by alterations in the character of the vessel walls. Accentuation of the aortic second sound is a normal phenomenon with age and occurs in such conditions as arteriosclerosis or syphilitic aortitis, which may cause diffuse change in the physical properties of the wall of the aorta. The other conditions which affect the intensity of the second sound are primarily those which alter pressures in the aorta and pulmonary artery, an increase in pressure tending to be associated with accentuation of the corresponding sounds.

The loud first sound of mitral stenosis is probably related not only to the thickening of the cusps but to the delay in onset of the mitral component because of the elevated left atrial pressure. Thus the normal splitting due to earlier mitral closure is absent, the mitral and tricuspid components are fused, and the first sound tends to be louder but briefer than normal. When the period elapsing between the start of excitation and mitral closure ($Q-S^1$ time) exceeds 0.07 sec, mitral stenosis is probable and the degree of prolongation bears a general relationship to the height of left atrial pressure and hence to the degree of stenosis.

Quality. Judgments concerning the state of the heart on the basis of the "quality" of the first sound are likely to be fallacious. The tic rhythm (embryocardia) of shock is a reflection of tachycardia and defective venous return. The diminished intensity which is so common in older persons is usually the result either of such extracardiac factors as emphysema or obesity or of a relatively long P-R interval caused by vagal tone. The functional integrity of the myocardium cannot be assessed by the intensity or pitch of the first heart sound. Other criteria should be utilized (Chap. 249).

Three-sound Rhythms. These fall into several general groups (Fig. 251-1). The additional sound may be heard in close approximation to the normal first or second sound, or in midsystole, or in mid-diastole.

Splitting of the First Sound. This is a normal phenomenon because closure of the mitral valve precedes that of the tricuspid by 0.01 to 0.02 sec. This splitting is usually best heard at the tricuspid area where the second and fainter component is loudest. It may be heard in a considerable propor-

FIG. 251-1. The middiastolic sounds due to a prolonged P-R interval or to a one-sound ventricular premature beat (see text) are not shown because their times are inconstant in relation to the cardiac cycle. The middiastolic extracardiac noises are likewise not indicated.

Because of their close temporal approximation, the ejection clicks cannot be separated from splitting of the first sound by auscultation. The presystolic rumble, when very brief, may be confused with an atrial gallop, but both may usually be distinguished from the other phenomena.

During relaxation and early filling, the split second sound may be confused with the opening snap, the normal third sound, the filling (protodiastolic) gallop, or with a filling rumble of unusually brief duration. The distinction between these several phenomena, while often possible by auscultation alone, sometimes requires simultaneous phonocardiograms, electrocardiograms, pulse tracings, and records of precordial movement.

tion of healthy persons. The distinction from the less frequent ejection sound usually requires graphic methods. The latter phenomenon is apparently due either to semilunar opening or to the sudden expansion of the great vessels and is usually best heard at the pulmonary area in persons with pulmonary hypertension. It may be recorded by sensitive techniques at the aortic or mitral areas in many normal persons but is rarely audible and has little practical significance.

When the P-R interval is normal, the very small vibrations of the atrioventricular cusps related to atrial activity are blended with the larger forces of the first heart sound and are usually inaudible. When, as occurs in the several types of heart block, this interval is abnormally long, the atrial sounds may be heard (see below). In patients with heart failure and regular rhythm, the force of atrial contraction is nearly always increased and, even though the P-R interval is normal, an audible sound—the *presystolic* or *atrial gallop*—is commonly noted. This phenomenon, although occasionally audible in the absence of heart failure, usually signifies that

failure is present or imminent and is, therefore, of practical importance. Just prior to atrial contraction, the atrial pressure is equal to that in the corresponding ventricle. A slight elevation of ventricular diastolic pressure causes relatively great stretch of the thin-walled and highly distensible atrium. Thus, in accordance with Starling's law, the changes in pressure as the atrium contracts and then relaxes are greater than normal. The resulting exaggerated tensing of the cusps is apparently responsible for the atrial sound.

The presystolic gallop may usually be distinguished from a split first sound by the longer interval (ta-lubb—dup, rather than t'lubb—dup). The differentiation from an exceptionally brief presystolic rumble, a rare source of confusion, can be made by listening after exercise, which increases the duration of the latter.

The *third sounds occurring during midsystole* are nearly always of extracardiac origin. They commonly arise from bubbles of air in the neighboring alimentary organs but may be due to pneumothorax or to mediastinal emphysema. In some instances, their site and mechanism are unknown, but they have no significance as regards the heart.

Splitting of the second sound is a normal phenomenon during inspiration, when the greater inflow into the right ventricle produces some prolongation of its ejection. The delay in pulmonic closure due to the lower pressure as compared with that in the aorta is normally very slight during expiration, and can be demonstrated only by graphic methods. Audible expiratory splitting, which is best heard in the tricuspid or pulmonary areas, is probably always abnormal when it is present in the sitting or standing position. It is usually but not invariably abnormal in the recumbent position. Such splitting may be due to delayed pulmonary closure because of an increased flow load involving the right ventricle only (interatrial defect or anomalous venous drainage with one or more pulmonary veins emptying into the right atrium) or, more rarely, to an increased pressure load from pulmonic stenosis. Although phonocardiograms may display the same phenomenon with right bundle branch block, the change is rarely so pronounced as to be of bedside diagnostic value in the latter condition. Unusually early aortic closure, such as occurs with mitral insufficiency, may also produce audible expiratory splitting.

In patients with large interatrial defects, the filling of the right atrium from the left may exceed that from the cavae. Hence the volume and duration of right ventricular ejection are not significantly increased by inspiration. Therefore, there is no inspiratory exaggeration of the splitting of the second sound. This phenomenon is of diagnostic value, i.e., a pronounced expiratory split which is not audibly

greater during inspiration is suggestive evidence for the presence of an interatrial defect.

The *opening snap* is occasionally due to tricuspid stenosis. Much more commonly, it is an important sign of mitral stenosis. Its time of onset after the second heart sound is inversely related to the height of the left atrial pressure. Thus a very short S²-OS time, like a very long Q-S¹ time, speaks for a high degree of mitral stenosis.

The opening snap is of brief duration, high-pitched, and usually best heard in the fourth or fifth space between the left sternal margin and the apex. These features will usually distinguish it from the split second sound which occurs somewhat earlier and is likely to be better heard at the pulmonic or apical regions.

Three sounds may be noted during the phase of rapid filling. Two of these, the physiologic third sound and the protodiastolic (filling) gallop, are apparently both due to a rapid equalization of pressure between atrium and ventricle, with headward rebound of the atrioventricular cusps. Although they occur at the same time, have the same low pitch, and are heard in the same (mitral or tricuspid) areas, they are not likely to be confused with each other. The physiologic third sound occurs in young persons and probably signifies rather complete ventricular emptying. In the case of the protodiastolic gallop, the rapid filling is due not to unusually low pressure in the ventricle but to elevation in the atrium and possibly also to some dilatation of the atrioventricular orifice. Thus we have the paradox of a somewhat similar phenomenon indicating either a vigorous or an impaired heart. The distinction is based on such associated findings as age, heart size, and the history of exercise tolerance. Furthermore, the normal third sound is usually best heard when the rate is slow, while moderate tachycardia is the rule in patients with the filling gallop. Because of this, the cadence resembling that of a cantering horse is usually present only with the latter condition.

Confusion between these two phenomena and a very brief filling rumble is rare and can usually be settled by exercise, which tends to prolong the latter phenomenon.

The filling gallop is of great practical importance. It is often the sole cardiac sign of heart failure, the other manifestations being found in the lungs or elsewhere. It may also be the earliest sign, preceding the congestive phenomena by months or even years. When, as is commonly true, it arises on the left side, it is best heard at the apex and is louder during expiration. However, right ventricular gallops occasionally occur. They are likely to be equally or more loud during inspiration and are best heard in the lower parasternal region or, when emphysema is present, in the epigastrium.

These several phenomena, which occur during early filling, may usually be separated from the split second sound and from the opening snap by their lower pitch and by their point of maximal intensity, which is ordinarily in a more inferior interspace. However, doubt may occur in a patient presenting signs of both stenosis and insufficiency of the mitral valve. Here, the distinction assumes great practical significance in relation to cardiac surgery. An opening snap speaks strongly for predominant stenosis, while a left ventricular filling gallop precludes marked narrowing of the valve because pronounced stenosis prevents the rapid pressure equalization which produces the gallop. Under this circumstance it may be necessary to make simultaneous recordings of heart sounds and of precordial motions, in order to learn whether the sound in question precedes the onset of filling (split sound), coincides exactly with it (opening snap), or appears 0.04 to 0.06 sec later (filling gallop). Even so, caution must be exercised to avoid confusion between (1) mitral insufficiency with both a rumble due to rapid filling and a left-sided filling gallop; and (2) mitral stenosis, as the cause of the rumble, associated with a right ventricular filling gallop (pp. 1412 and 1440).

The pansystolic murmur of mitral insufficiency may continue during relaxation and thus mask the second sound at the apex. Under this circumstance the filling gallop may be mistaken for the second sound.

Being low-pitched, the protodiastolic gallop is best heard with a bell-type stethoscope, using gentle pressure. It is ordinarily the faintest of the three sounds but may be the loudest. This confusing sign is especially common when the rate is rapid, diastole short, and the atrial and filling gallops are superimposed during rapid filling (summation gallop).

Although rubs, murmurs, or even extracardiac noises may be heard during middiastole, true heart sounds are rare at this time of the cycle. When the P-R interval is long, the faint vibrations of the valves induced by atrial activity may produce a low-pitched and faint but audible sound. It is important to separate this from the single sound caused by a very premature ventricular beat which is too feeble to open the semilunar valves and hence causes no second sound. Either phenomenon may occur in middiastole. In most instances, the premature beat has a higher pitch. However, the differentiation may be impossible by auscultation. This is almost the only situation in which the electrocardiogram will supply crucial information concerning the exact nature of heart sounds. Such a tracing should always be made because both conditions—heart block and frequent premature beats—may require treatment and the drug which is indicated

FIG. 251-2. The onset, offset, and "shape" (*crescendo*, *diminucendo*, or *diamond*) of murmurs in relation to the pressure differences between adjacent areas are illustrated. P and Q indicate the onset of atrial and ventricular excitation, respectively.

Note that the murmur of mitral insufficiency starts with the beginning of the first sound (M'), and endures beyond the second, or until the pressure in the left ventricle (LVP) falls below that in the left atrium (LAP). In contrast, the "diamond" murmur of aortic stenosis starts later, as ejection begins. It increases and then decreases in intensity, according to the pressure gradient between the left ventricle and the aorta (AoP), and ceases just before the aortic second sound (A') as these pressures become equalized.

The murmur of aortic insufficiency starts with the second sound because the left ventricular pressure falls below the aortic at this time. The filling rumble of mitral stenosis begins later as the ventricular pressure descends below the atrial. The presystolic accentuation of the stenotic murmurs occurs as the left atrium contracts.

for one of them may be seriously hazardous for the other (p. 1405).

MURMURS

The discussion to follow is concerned primarily with murmurs arising in the heart, and only incidentally with those in other areas. It deals with the mechanisms and types of murmurs and their general significance but not with the specific causative lesions, which are considered in the next two chapters.

Most murmurs are limited to systole or diastole; a few are continuous. Diastolic murmurs always mean organic disease, and the main problem is that of hearing them. Systolic murmurs are more readily heard, may or may not signify a structural disorder, and the chief question is that of interpretation. In this regard a rheumatic history, an associated thrill, or the demonstration of a calcified valve may be of crucial importance.

The precise time of onset and of offset of murmurs depends on the point of the cardiac cycle at which an adequate pressure difference between two chambers appears and disappears. This general principle, which is considered in some detail in subsequent pages, is illustrated in Fig. 251-2. Inspection of this diagram will reveal the reasons why murmurs are called *pansystolic*, *ejection*, *late systolic*, *regurgitant*, *early filling*, and *presystolic*.

The accentuation of a murmur during inspiration

means that it is almost certainly arising on the right side of the heart, the effect of the augmented venous return predominating over the damping tendency of lung expansion. Expiratory exaggeration has less significance. It is the rule with left-sided murmurs but may also occur with those arising in the right chambers if the intensifying result of reduced lung volume predominates over the hemodynamic effect of reduced venous return.

There is no simple relation between the loudness of a murmur and the severity of the responsible lesion. Thus in the advanced stages of mitral stenosis the diastolic rumble may actually decrease because of diminished flow through the orifice. Similarly, in patent ductus arteriosus the development of secondary pulmonary hypertension, with aggravation of the patient's symptoms, may be associated with reduced intensity of the murmur as the left-to-right shunt diminishes.

The murmurs of aortic and pulmonic stenosis are low-pitched and "rough" because they are related to the low-frequency vibrations of the semilunar cusps. However, the insufficiency murmurs, being due to vibrations (eddies) of blood, are higher pitched and resemble the swishing sound of a mountain stream.

Murmurs and Turbulence. When a liquid or a gas moves, not in smooth straight lines but in constantly changing directions and velocities, the flow is said to be turbulent. Murmurs, wheezes, and the sounds of mountain streams are the results of tur-

bulence, which tends to be produced by rapid velocity, by irregularity or increase in stream-bed diameter, and by high density of the flowing fluid. The latter influence presumably accounts for the beneficial effect on wheezing of helium, which is much lighter than nitrogen. Turbulence varies inversely with viscosity. Therefore, murmurs tend to occur in anemic patients, even if the volume and velocity of flow remain constant. Actually, they usually increase, and this also favors the production of murmurs.

These considerations explain many aspects of murmurs: their frequent occurrence during systole in vigorous young hearts (high velocity of flow), their appearance even in diastole when flow is sufficiently rapid (the "pseudostenotic atrioventricular rumbles" in patients with atrial septal defect, patent ductus, or even with uncomplicated mitral insufficiency); their presence with stenotic lesions (for a given total flow the velocity is inversely proportional to the square of the orifice size). Insufficiency murmurs are related not only to the high velocity because of the large pressure difference between the respective chambers, but also to the additional turbulence caused by the convergence of two streams of blood.

The bruits heard over aneurysms are related to the increase in diameter. The murmur caused by the increase in velocity at the site of a narrowed vessel is usually systolic only because collateral circulation above the constriction reduces the diastolic pressure gradient; when collaterals are absent, partial occlusion may cause a continuous murmur.

The energy (pressure gradient) necessary to produce a given volume flow is proportional to V (velocity) when the flow is laminar but to V^2 when it is turbulent. Thus a stenotic lesion exerts two harmful mechanical effects—that due to the narrowing per se and that due to the turbulence secondary to the narrowing. As the velocity of flow increases with exercise, the second effect becomes progressively more important, as shown by increasing loudness of the murmur.

Systolic Murmurs. These may be divided into three groups in relation to their time.

Pansystolic Murmurs. This group includes those murmurs involving two chambers which have widely different systolic pressures, such as the left ventricle and either the left atrium or the right ventricle. The pressure gradient is established very early in contraction and lasts until relaxation is almost complete. Thus such murmurs begin during isometric contraction and at the area of maximal intensity tend to mask both heart sounds because they begin with the first and cease after the second. The pansystolic murmurs due to ventriculoatrial regurgitation may be dependent either on deformation of the cusps ("organic") or on dilatation of the

rings ("relative"). The latter murmurs are associated with well-marked cardiac enlargement and become fainter with improvement of heart failure. The organic regurgitant murmurs may occur in hearts of any size and, when accompanied by congestive failure, are likely to become louder as improvement occurs.

Pansystolic murmurs are not found in patients with interatrial defects unless there is atrioventricular regurgitation due to associated deformities of the mitral or tricuspid valves. In the case of those interventricular shunts which are accompanied by a large pressure gradient between the two ventricles, these murmurs do occur. Large openings in the interventricular septum usually lead to early pulmonary hypertension, which raises the right ventricular systolic pressure and thus tends to reduce the shunt. Furthermore, the turbulence is related to the velocity of flow which, if pressures are constant, is inversely proportional to the square of the size of the orifice. A high pressure gradient is likely to be associated with a high-pitched murmur. These considerations explain why the small and relatively innocent defects of the muscular part of the septum are likely to be associated with louder murmurs of higher pitch than the larger and more serious shunts which are situated higher and involve the membranous portion. In the latter circumstances the faint pansystolic murmur may be overshadowed by the louder ejection blow caused by the relative stenosis consequent to increased flow through the dilated pulmonary artery.

Ejection Murmurs. These are related to a disproportion between the flow and the size of the orifice. Even though the semilunar valves are normal, a large flow or dilated vessel may be responsible. Narrowing of the outflow tract or of the valves may cause such a murmur, the intensity being related to the flow. Thus the murmur of aortic stenosis becomes faint and may disappear during heart failure and return with great intensity following digitalization.

The ejection murmurs start shortly after the first sound and do not actually replace it, although this may seem to be the case by auscultation. As the ventricular pressure rises and declines during ejection, the murmur becomes louder and then fainter. This "diamond shape" is readily seen in phonocardiograms but may not be apparent to the ear. The second heart sound may be exaggerated or normal and is not obscured by the murmur, which ceases before semilunar closure occurs. However, when stenosis of one of the valves is responsible, the corresponding second sound may be faint or absent because the cusps are no longer pliable.

The age of the patient and the area of maximal intensity are of great importance in determining the significance of ejection murmurs. Thus in a

young adult with vigorous contraction and a high ejection velocity, a faint or moderate ejection blow heard only in the pulmonary area is usually without significance, while a similar murmur in the aortic area is likely to indicate stenosis of the valve or some congenital abnormality. In elderly persons, functional pulmonic blows are rare, while aortic systolic murmurs may be due to dilatation or roughening of the aorta, to left ventricular hypertrophy with vigorous contraction and functional stenosis of the left ventricular outflow tract, to an important degree of aortic stenosis, or to slight narrowing of the valve. The latter condition, when associated with a high level of cardiac output, may produce a loud murmur even though the stenosis is of no hemodynamic importance, as shown by the lack of a significant pressure gradient between the left ventricle and the aorta.

The most common ejection murmur is that heard at the pulmonary area in healthy young persons with small and vigorous hearts. It is probably due to the combination of a high velocity of flow and a thin chest wall. When it is faint (grade I or II), blowing, and unassociated with evidence of disease, the diagnosis of an innocent functional murmur will be apparent. Less frequently, the quality is rough and the intensity may be grade III or IV. Such patients, who are called "paranormals," are frequently anxious and may have multiple cardiovascular complaints. Under these exceptional circumstances, cardiac catheterization may be necessary in order to separate such an exaggerated functional murmur from one due to a slight congenital deformity. However, careful attention to the second heart sound may yield an important clue (p. 140S). Audible expiratory splitting indicates that the duration of right ventricular ejection remains long and its stroke volume large, despite the diminished systemic venous return during expiration. This suggests that a large fraction of the blood entering the right ventricle is coming from intrathoracic structures. Pronounced and audible expiratory splitting of the second sound in a person with an ejection murmur, therefore, points toward a defect of the interatrial septum or anomalous drainage of one or more pulmonary veins into the right atrium. Inspiratory splitting, a normal phenomenon, has no diagnostic significance.

Late Systolic Murmurs. Many patients with coronary disease present faint or moderate (rarely loud) blowing apical systolic murmurs which seem to start well after ejection and do not mask either sound. The exact mechanism responsible for them has not been clarified. Since they may be much louder or heard only during anginal attacks, it is probable that they are related to ischemia of the papillary muscles or, possibly, to distortion of these structures by the ischemic bulges (functional aneu-

rysms), which so commonly occur following infarction or during anginal episodes (p. 35).

The late systolic murmurs which occasionally occur in young subjects are usually musical or "whistling." Their mechanism is not known. In most instances, there is no evidence of cardiac disease and the murmurs are without significance. Rarely, such a musical or squeaking late systolic murmur is seen in a young person with undoubted rheumatic heart disease. In such an instance, the differentiation from the similar innocent murmur will depend on the associated findings.

Diastolic Murmurs. These also include three main types.

Regurgitant Murmurs. The regurgitant diastolic murmurs begin with or shortly after the second heart sound, or as soon as the corresponding ventricular pressure falls sufficiently below that in the aorta or pulmonary artery. Since they are mainly due to eddies of blood rather than to vibrations of valve cusps, they have a high-pitched swishing quality resembling breath sounds. They are best heard during held forced expiration, with the patient leaning forward or on his hands and knees. The high-frequency vibrations are best detected by a diaphragm stethoscope or by firm pressure, if a bell is used.

Regurgitation through the aortic valve is usually due to deformity of the cusps rather than to dilatation of the annulus. The reverse is true of pulmonic insufficiency. The differentiation of these conditions is discussed in a later chapter (p. 1442).

Filling Murmurs. Diastolic murmurs during early filling are, like ejection blows, due to disproportion between orifice size and flow rate. Thus mitral and tricuspid stenosis are associated with rumbles which start soon but at an appreciable interval after the second sound. With normal or high flow, such murmurs may be loud when stenosis is slight. Conversely, a high degree of obstruction may cause a very faint or even no rumble if cardiac output is sufficiently reduced. When stenosis is marked, ventricular filling is inevitably prolonged. Thus the duration of the murmur is more reliable than the intensity as an index of the degree of narrowing.

Despite normal mitral cusps, patients with aortic insufficiency may have a diastolic mitral rumble (the Austin-Flint murmur). This is probably due to vibration of the aortic cusp of the mitral valve between the normal and abnormal streams of blood into the ventricle.

A faint diastolic murmur heard in a patient with acute rheumatic fever may sometimes disappear. In such an instance (Coombs's murmur) edema of the mitral cusps is probably responsible.

Very high rates of flow may cause loud but brief filling rumbles, despite normal cusps, at either atri-

oventricular orifice. In the case of the tricuspid valve, the usual cause is a large interatrial defect. Such "relative stenosis" of the mitral valve is seen in patients with patent ductus and is particularly confusing when mitral insufficiency with minimal or no stenosis is the cause. Aside from the duration of the rumble, the intensity of the first sound, the presence or absence of a well-marked opening snap, and the type of hypertrophy are important guides to the predominant lesion (p. 1439).

Presystolic Murmurs. The *presystolic* or *atrial systolic* murmur is usually due to mitral (rarely tricuspid) stenosis. It has the same quality as the filling rumble but is usually crescendo rather than decrescendo. Because of its short duration it may be confused with an atrial gallop or a split first sound. Its accentuation and prolongation, due to fusion with the filling rumble, by exercise will usually make the distinction.

When these filling rumbles, whether early or presystolic, arise at the mitral orifice, they are best heard with a bell stethoscope at the exact point of the apex, while the patient lies on the left side and during expiration. Occasionally, they are audible only after exercise. The tricuspid rumbles, which are much less common, are heard in the left parasternal region and are sometimes louder during inspiration.

Continuous Murmurs. These signify continuous flow due to a communication between a high-pressure and a low-pressure area, without an intervening valve. The commonest cause is patent ductus arteriosus, which causes a continuous murmur as long as the pressure in the pulmonary artery is much below that in the aorta. When pulmonary hypertension due to left-sided failure or to arteriolar changes in the lungs supervenes, the duration of the murmur lessens and it may eventually disappear or persist only during systole.

Less common causes of continuous murmurs include systemic or pulmonary arteriovenous fistula, the development of marked bronchial collateral circulation in patients with pulmonary stenosis, rupture of an aortic aneurysm into the pulmonary artery, and a congenital window between the roots of the aorta and pulmonary artery. Coarctation of the aorta and stenosis of a main pulmonary artery usually cause systolic murmurs only, but when because of poor collaterals proximal to the obstruction the pressure gradient remains large throughout diastole, this murmur may be continuous.

Rupture of a sinus of Valsalva into the right atrium or ventricle is a rare but surgically curable cause of a continuous murmur which, under this circumstance, may be loudest in the lower sternal region.

The cervical venous hum or *bruit de diable* is a faint continuous musical murmur at the base of the

neck. Gentle pressure by the stethoscope causes it to disappear. It has no significance.

Significance of Murmurs. All diastolic murmurs and, with the exception of the cervical venous hum, all continuous murmurs indicate structural disease. The systolic bruit, when very loud or associated with a thrill, has the same significance. The problem of interpretation arises with the moderately loud systolic blow, which usually is due to an organic lesion and, especially, with the faint (grade I or II) systolic murmur. Here, the decision will depend on consideration of all the evidence and will sometimes be in doubt, even after cardiac catheterization. Small left-to-right shunts may be overlooked unless the newer methods, such as the hydrogen electrode, are utilized. In borderline instances, a faint systolic murmur, loudest at the base, should be considered innocent until proved otherwise. A similar murmur heard only at the apex is more likely to be of structural origin. Even so, if there are no other signs of organic heart disease, the only therapeutic considerations are those of prophylaxis against rheumatic fever and bacterial endocarditis (pp. 918 and 1043).

Thrills. In the region of the apex, thrills are of limited diagnostic import because they may be confused with vibrations set up by a vigorously beating heart. On the other hand, the presence of a thrill at the base of the heart or along the left sternal border constitutes practically conclusive evidence that the accompanying murmur is of the organic type. It is true that thrills are simply the tactile equivalent of the auditory basis of the murmur and hence have no greater significance than the murmur itself. It happens, however, that the kind of murmur which gives rise to vibrations that can be felt as a thrill is almost invariably of organic origin. Such thrills are of especial importance in the diagnosis of aortic stenosis.

The *pericardial friction rub* may occasionally be confused with a harsh systolic murmur or with an insignificant adventitious sound ("sternal crunch"). Such uncertainty, which arises when the rub is only systolic, will be solved by consideration of the total clinical picture. The characteristic to-and-fro squeaking sound signifies pericarditis and is nearly always accompanied by other findings of this disorder (p. 1467).

ELECTROCARDIOGRAPHY IN THE DIAGNOSIS OF CARDIAC DISEASE

In patients with arrhythmias, the electrocardiogram usually supplies precise information. Under other circumstances, the records are likely to lead to erroneous conclusions unless evaluated in relation to the total picture. Variations in the placement of precordial electrodes during successive

tracings may lead to an erroneous conclusion that an acute myocardial disorder is present because of "changes" in the record. Similarly, a chest deformity or an unusually low diaphragm, with a vertical position of the heart, may be associated with an "abnormal" record when the precordial electrode is placed in the usual positions. Such errors may be avoided by securing each V lead from multiple interspaces. Certain innocent electrocardiographic findings which are likely to be misinterpreted are illustrated on p. 1446.

Abnormalities in the form of the ventricular complex are often erroneously evaluated. There is strong evidence that the Q-R-S-T sequence is mainly dependent on the subepicardial portions of the ventricle and that the subendocardial fibers are electrically silent. Therefore, subepicardial fibrosis due to such innocent causes as healed focal pericarditis or remote contusions of the heart may cause impressive changes in the electrocardiogram, while an extensive recent subendocardial infarction may show no significant change. T waves are especially labile and may be altered by electrolyte shifts, emotion, tachycardia, pressure on the ventricle, ingestion of food drinks, or even by a carbohydrate-rich meal. The QRS complex is less unstable, and the presence of Q waves of 0.04 sec or longer duration has greater or lesser significance as a sign of focal myocardial disease, depending on the leads in which the Q waves occur. However, there is no necessary parallelism between such a change and the gravity of the clinical picture, or even the nature of the underlying disease process. It so happens that coronary disease is the commonest cause of focal myocardial disease, but identical changes may be induced by other localized disorders such as abscess or tumor. Thus, except in patients with arrhythmias, therapy should be based on the clinical picture. Diagnosis is based on evaluation of all the evidence, with emphasis in most instances on that derived from the clinical study.

OTHER DIAGNOSTIC PROCEDURES

The importance of the fluoroscopic examination has already been mentioned. Certain methods, such as cardiac catheterization, angiocardiology, and oximetry, which are widely used in the study of congenital lesions, are considered in Chap. 252, which deals with those disorders.

In the hands of those who are experienced with them, the ballistocardiographic, electrokymographic, and kinetocardiographic techniques yield certain information of practical value. Their main present value, however, is in the field of research.

For a more detailed consideration of physical signs in relation to specific congenital and acquired

lesions, the reader is referred to the two succeeding chapters.

252 CONGENITAL HEART DISEASE

William R. Milnor and
Henry T. Bahnson

The demonstration that many congenital malformations of the heart can be treated successfully by surgery has radically changed the physician's approach to congenital heart disease. Not long ago the nonspecific clinical diagnosis of *congenital heart disease* was regarded as all that was possible or necessary in many cases. Today, the accurate recognition of specific lesions and a quantitative estimate of the burden they impose on the heart in each case is of great practical importance.

Incidence. Congenital heart disease occurs in approximately 0.3 per cent of all live births, and congenital malformations constitute 1 to 5 per cent of all cases of recognized heart disease after infancy.

Etiology. Many abnormalities of the heart and great vessels can be explained by failure to progress beyond an early stage of embryologic development, while others seem to represent aberrant development of a normal structure. The cause of these embryologic misadventures is unknown in most cases, but various theories involving fetal hypoxia, fetal endocarditis, immunologic abnormalities, vitamin deficiencies, and specific genetic abnormalities have been proposed.

In some cases a clear relation between maternal rubella during gestation and congenital malformations of the heart has been demonstrated. It appears that maternal rubella during the first 2 months of pregnancy will lead to congenital malformations

of the heart, cataracts, deaf-mutism, or other anomalies in almost all cases. The later in gestation the rubella occurs, the lower the incidence of congenital abnormalities, but cases of congenital heart disease have occurred following rubella in the sixth month of pregnancy. In clinical practice, however, relatively few cases of congenital heart disease—probably less than 2 per cent—can be attributed to this cause, and in most instances no significant environmental factor during fetal development can be elicited by history.

Inheritance. With few exceptions, patients with congenital heart disease have a negative familial history for congenital malformations. There are, nevertheless, well-documented exceptions, including families in which the same malformation has recurred in two or three successive generations. Patent ductus arteriosus is the commonest lesion thus reported, but this may simply reflect the relatively benign course of this anomaly.

The birth of one child with a congenital malformation of the heart does not in itself contraindicate future pregnancies, since the risk that subsequent siblings will have congenital malformations is extremely small.

There is good evidence that factors concerned with some congenital malformations can be transmitted as mendelian recessive traits, while others may arise as a result of mutation *de novo*. In at least one heritable disorder of connective tissue (Marfan's syndrome, p. 1884) cardiovascular manifestations are a prominent feature.

The incidence of some congenital malformations of the heart shows clear sex differences, which may be attributed to either sex-linked inheritance or environmental factors in utero. Defects of the atrial septum and persistent patency of the ductus arteriosus are much more common in females than in males; pulmonic stenosis and ventricular septal defect show little or no sex difference; coarctation of the aorta and congenital aortic stenosis affect males predominantly.

PHYSIOLOGIC EFFECTS

Shunts

A cardiovascular shunt may be broadly defined as blood flow through an abnormal pathway. It requires an open communication (or one potentially open, such as a patent foramen ovale) between the pulmonic and systemic circulations. The direction and degree of blood flow are determined by the dimensions of the opening and the pressures existing on either side of it. Such communications usually represent persistence of an embryonic stage of development into postnatal life.

In some cases changing pressure gradients during the heart cycle will produce shunts that vary in direction. In other instances the existence of roughly equivalent pressures on opposite sides of a defect may prevent shunting of blood, even if the defect is large. Streamlining of flow is an important factor in some instances and may produce shunting in the absence of measurable pressure gradients.

Left-to-Right Shunts. In this situation, a portion of the blood which flows through the lungs is diverted before reaching the systemic capillaries and is recirculated through the pulmonary bed. The volume of blood pumped through the pulmonary capillaries therefore exceeds the systemic flow per minute, unless complicating shunts in the opposite direction are also present. Pulmonic blood flows of 12 to 15 liters per min, with systemic flows of 4 to 5 liters per min, are common, and the ratio of pulmonic/systemic flow may reach 20 or more. In the latter situation, however, the difference in oxygen saturation between arterial and venous blood is so small that accurate calculation of pulmonary flow by the usual methods of cardiac catheterization is impossible.

With left-to-right shunts at the atrial or ventricular level, the right ventricle is required to pump an increased volume of blood per minute, at pressures which may or may not be higher than normal. This results in right ventricular dilatation and hypertrophy, the degree of hypertrophy being roughly proportional to the degree and duration of pulmonary hypertension. When the shunt is at the level of the pulmonary artery, as in patent ductus arteriosus uncomplicated by pulmonary hypertension, only the left ventricle hypertrophies; when pulmonary hypertension appears, right ventricular hypertrophy is superimposed.

Left ventricular work is increased if the site of the shunt is in the ventricular septum or distal to the left ventricle. Left ventricular hypertrophy and dilatation result but may be overshadowed by simultaneous right ventricular hypertrophy.

Atrial unsaturation does not occur with pure left-to-right shunts, but clinical cyanosis may occasionally be present as a result of decreased systemic flow or inadequate oxygenation in the lung. The latter is rare.

Auscultatory findings with left-to-right shunts depend on the specific malformations. When the shunt is distal to the mitral valve, an apical mid- or late diastolic murmur is often present, presumably because the greatly increased blood flow across a normal mitral orifice is equivalent to relative mitral stenosis. A similar diastolic murmur is sometimes present in cases of atrial septal defect, and may be due to relative tricuspid stenosis.

Right-to-Left Shunts. In this condition systemic venous blood returning to the heart enters the left

heart chambers or systemic arterial circuit without passing through the pulmonary capillary bed.

The major signs and symptoms accompanying right-to-left shunts result not only from the diversion of blood through abnormal pathways but also from the obstruction to blood flow through normal pathways (e.g., pulmonic stenosis) which is often present. The functional effect of these abnormalities is to reduce the partial pressure of oxygen in arterial blood and to burden one or both ventricles with extra work. Some of the resulting signs and symptoms are common to many different malformations and will be discussed individually.

Cyanosis. Cyanosis, or the appearance of clinically recognizable blueness in the systemic capillaries, is usually a direct result of lowered arterial oxygen saturation. Slowed peripheral blood flow and inadequate saturation in the lungs can also cause cyanosis, but these factors are of secondary importance in cyanotic congenital heart disease. The oxygen saturation of the blood leaving the lungs is usually normal, but the admixture of venous blood distal to the site of the right-to-left shunt reduces the arterial saturation. The degree of arterial unsaturation varies directly with the volume of the venous-arterial shunt, and inversely with the volume of pulmonary blood flow.

Cyanosis is best observed in the nail beds, buccal mucous membranes, and lips. It becomes evident clinically only when the equivalent of approximately 5 Gm per 100 ml unsaturated hemoglobin is present in arterial blood; hence patients with anemia may not show clinical cyanosis even though the oxygen saturation of arterial blood is well below normal, while polycythemia accentuates cyanosis with even minimal degrees of arterial unsaturation.

In congenital heart disease, cyanosis usually implies the existence of an abnormal communication between the venous and arterial sides of the circulation, which may be a patent foramen ovale, defect of the interatrial or interventricular septum, transposed great vessels, patent ductus arteriosus or other communication between the aorta and pulmonary artery, or (rarely) direct entry of systemic veins into the left atrium. In addition to the abnormal communication, hemodynamic conditions must be such that blood flows through the opening from "right to left," producing a venous-arterial shunt; this usually requires elevation of right atrial, right ventricular, or pulmonary artery pressure above normal levels. An extreme example of a structural anomaly which produces a right-to-left shunt is seen in complete transposition of the great vessels, in which the right ventricular outflow enters the aorta instead of the pulmonary artery. In occasional cases, clinical cyanosis may be due to diminished peripheral flow or other factors, as in the normal

vigorously crying child. It is almost never due to inadequate pulmonary oxygenation.

Polycythemia. Polycythemia with red cell counts of 6 to 9 million per cu mm, and hematocrits as high as 80, develops in response to the lowered arterial oxygen tension. The oxygen-carrying capacity of the blood is thereby increased, partially compensating for the decreased oxygen saturation. In many cases the increase of circulating hemoglobin is such that the oxygen content of the arterial blood is actually higher than normal.

The polycythemia is absolute rather than relative, i.e., the total red cell mass is increased. The plasma volume is usually decreased, but the red cell volume increase is of such magnitude that total blood volume is greater than normal.

This adaptive response is not entirely beneficial, since the blood viscosity increases as the hematocrit rises. The resulting increase in heart work is undesirable, but of even greater significance is the tendency to vascular thromboses. Hemiplegia and other cerebrovascular accidents occur frequently in polycythemic congenital heart disease. Dehydration is particularly to be avoided in these patients, since further reduction of plasma volume increases the predisposition to thromboses. In some patients with cyanotic congenital heart disease, polycythemia is accompanied by thrombocytopenia and low blood fibrinogen levels, leading to impaired clot retraction. Severe postoperative bleeding following the surgical repair of congenital cardiac defects can sometimes be attributed to this deficiency.

Clubbing. Clubbing of the fingers, and less often of the toes, is usually found in patients who have had cyanosis and polycythemia over a period of years. The pathogenesis of such clubbing is unexplained, but it may represent excessive growth of local tissue due to increased blood flow. Clinically identical clubbing may occur with pulmonary abscess or other diseases of the lung.

Impaired Growth. Impaired growth and development in children has been attributed to tissue hypoxemia in venous-arterial shunts, but it is open to question whether such a causal relationship exists. Some children with congenital heart disease are unquestionably stunted in growth and development, while others develop normally. Underdevelopment may be associated with malnutrition from inadequate feeding, or with the frequent respiratory and other infections to which these children are prone, or it may represent a concomitant congenital defect.

Squatting. Many patients with tetralogy of Fallot, and some with other lesions which obstruct blood flow to the lungs, find that squatting with the knees drawn up to the chest is the most comfortable resting position. They are uncomfortable, and often show increasing cyanosis, if made to stand

quietly, or if they are tilted passively on the fluoroscope table. Their avoidance of postures in which the legs are dependent suggests that decreased venous return is the important factor in these phenomena, but the mechanism is not well understood. Squatting is also observed in many normal children, and is a habitual resting position of adults in many parts of the world. The posture is clinically significant only if it can be shown to give symptomatic relief after exertion.

Paradoxic Embolism. This condition, in which emboli arising in the systemic veins travel through a defect and lodge in a peripheral artery, is always possible with right-to-left shunts. This is probably responsible in part for the increased incidence of brain abscess in these patients.

Pulmonary Hypertension

In the normal adult the pulmonary circulation is a relatively low-pressure system. Mean pulmonary artery pressures of 15 mm Hg, or about 10 mm Hg higher than mean left atrial pressure, are sufficient to maintain adequate blood flow through the lungs at rest. When the cardiac output is increased by exertion, the normal pulmonary vascular bed is so distensible that pulmonary blood flow can be doubled with very little increase in pulmonary artery pressure.

Two different mechanisms commonly give rise to pulmonary hypertension in congenital heart disease: greatly increased pulmonary blood flow and increased pulmonary arteriolar resistance. Increased resistance to pulmonary venous outflow, as in mitral stenosis or left ventricular failure, is a third cause of pulmonary hypertension, but is more common in acquired heart disease.

The increased pulmonary blood flow accompanying large left-to-right shunts is often four to five times the normal flow, which requires increased pulmonary artery pressure even when the pulmonary vascular bed is normal. In these circumstances pulmonary vascular resistance, which is defined as the pressure drop across the pulmonary bed (mm Hg) per unit of pulmonary blood flow (liters/min/m²), remains normal or even decreases if the vessels are readily distensible. Pulmonary hypertension of this type is usually moderate in degree, with mean pulmonary artery pressures less than 40 mm Hg.

Increased pulmonary vascular resistance due to narrowing or partial obliteration of pulmonary arterioles, on the other hand, makes necessary an increased perfusion pressure to maintain even normal flow, so that pulmonary artery pressure rises without a proportionate increase in flow. In some cases this increased arteriolar resistance is predominantly due to irreversible structural changes, while in others vasoconstriction plays the dominant role. Pulmonary vascular resistance in this latter

group can be temporarily lowered by inhalation of 100 per cent oxygen or by injection of acetylcholine and usually falls after successful correction of the accompanying cardiovascular defect.

Pulmonary vascular resistance is normally high at birth, and the small pulmonary arteries possess thick walls and relatively narrow lumina characteristic of the fetal circulation. After birth the arterial walls gradually become less thick and pulmonary vascular resistance falls. In patients with large communications between the ventricles or between pulmonary artery and aorta, the fetal structure of the pulmonary arteries persists into adult life; pulmonary hypertension is found in infancy and cyanosis appears early. Smaller communications between the ventricles, atria, or great vessels are usually accompanied by normal regression of pulmonary vascular resistance during infancy. The pulmonary arteries assume the normal thin-walled postnatal structure and remain normal throughout childhood or longer. In many of these cases the pulmonary vascular resistance eventually begins to rise, although the onset varies from adolescence to the fifth decade.

It seems clear that the absolute magnitude of pulmonary blood flow is not the only factor which influences the development of pulmonary hypertension. Abnormally high pulmonary artery pressures are found more often with ventricular than with atrial septal defects, and only occasionally with patent ductus arteriosus, although pulmonary blood flow is often three or more times the systemic flow in all these abnormalities.

The significance of pulmonary hypertension in each case, therefore, depends on its duration, the site and size of the cardiovascular defect, the anatomic changes in the pulmonary vessels, and the part played by active vasoconstriction. The desirability of correcting defects before irreversible pulmonary vascular changes have taken place whenever possible and the increased operative risk in patients with extremely high pulmonary vascular resistance are factors that play a large part in deciding on surgical therapy.

The most important clinical effects of pulmonary hypertension are: (1) *Right ventricular hypertrophy*, with characteristic left parasternal thrust and changes in the electrocardiogram and roentgenogram. If the strain on the right ventricle is too severe or too prolonged it may fail, with the same increased venous pressure, distention of the liver, and peripheral edema seen in right ventricular failure from other lesions. (2) *Enlargement of the pulmonary artery and its main branches*, which can be recognized by fluoroscopy or roentgenography. Precordial pain (p. 34), coming on either spontaneously or with effort, is frequently a troublesome symptom in patients with a dilated pulmonary

artery and pulmonary hypertension. (3) *Cyanosis*, if the right-sided pressures rise enough to produce a right-to-left shunt through the existing defect.

The principal auscultatory signs of pulmonary hypertension are accentuation of the pulmonic component of the second sound, often with splitting, and a systolic murmur in the pulmonic area attributable to turbulence as blood is ejected into the dilated pulmonary artery. Such murmurs may be as loud as grade 4, but are not usually accompanied by a thrill. When the pulmonary artery is greatly dilated, there is sometimes an extra sound early in systole ("systolic click").

Primary pulmonary hypertension is characterized by increased pulmonary vascular resistance in the absence of cardiovascular shunts or other abnormalities that are known to produce pulmonary hypertension. A similar disease in adults (p. 1338), seen most often in women between twenty and thirty-five years, appears not to be congenital in origin, but is usually fatal within a few years after the onset of symptoms. The condition is rare, and many suspected adult cases prove to be due to multiple small pulmonary emboli or to intracardiac shunts which had not been detected clinically.

SPECIAL DIAGNOSTIC METHODS

Röntgenography. The importance of roentgenographic examination in congenital heart disease can hardly be overstated. Fluoroscopic examination should be carried out in every patient suspected of having a cardiac malformation, and full-size chest films in the posteroanterior and oblique positions, with barium in the esophagus, should be recorded. The size and position of the great vessels and heart chambers, the vascularity of the lung fields, and the pulsations observed during fluoroscopy are often the deciding clues in differential diagnosis. Characteristic configurations in some congenital anomalies of the heart are shown in Fig. 252-1.

Angiocardiography. The introduction of radioopaque solutions into the blood stream to demonstrate the course of the blood and to outline the chambers of the heart is often of great help in diagnosis. Angiocardiography is most helpful with complex malformations in which data from catheterization are inadequate or equivocal, particularly when there is some uncertainty as to how blood reaches the lungs or which ventricle communicates with the systemic circulation.

The solution may be introduced through a peripheral vein, but injection directly into the heart through a catheter (selective angiocardiography) allows the use of smaller volumes and gives a more satisfactory visualization of intracardiac structures. Motion pictures of the fluoroscopic image (cine-

angiocardiography) give an essentially continuous record of the passage of the contrast medium and may show details not readily appreciated in single films.

The mortality associated with these procedures is in the neighborhood of 0.3 per cent. As with cardiac catheterization, the hazard is greatest in the presence of pulmonary hypertension or cyanosis.

Electrocardiography. In congenital heart disease the principal contribution of electrocardiography is the determination of specific ventricular hypertrophy, and it is often more sensitive for this purpose than roentgenography. Right ventricular hypertrophy and enlargement are common with many types of congenital malformation. In the most extreme examples of right ventricular hypertrophy the QRS axis may come to point over the right shoulder, giving prominent S waves in standard lead III which may erroneously be interpreted as left axis deviation. The amplitude of the QRS complexes is as important as the QRS axis in evaluating ventricular hypertrophy. QRS changes are always more specific than T-wave abnormalities in indicating which ventricle is involved.

Prolongation of the QRS duration beyond 0.12 sec is uncommon in congenital heart disease. An rS¹ complex in precordial lead V, and adjacent leads occur frequently with right ventricular hypertrophy, but the duration usually ranges from 0.08 to 0.11 sec. This pattern has been termed "incomplete right bundle branch block" when the QRS duration is 0.10 to 0.12 sec, but the clinical significance in this situation is the same as with shorter QRS durations. The Wolff-Parkinson-White conduction anomaly is not common in congenital heart disease, except in Ebstein's anomaly.

Prolonged P-R intervals are particularly frequent with atrial septal defect and are found occasionally in other malformations. Complete atrioventricular block is rare. Although it is said to be common in ventricular septal defects, its incidence in this anomaly has probably been overestimated. Congenital complete heart block is a rare functional abnormality which may occur in the absence of other defects and is usually of no functional consequence.

Supraventricular arrhythmias, including atrial fibrillation and flutter, atrial and nodal tachycardia, and wandering of the pacemaker, occur with many malformations, particularly with atrial septal defect and with Ebstein's anomaly. Ventricular arrhythmias are no more frequent than in acquired heart disease.

Cardiac Catheterization. Information obtained by catheterization of the right side of the heart has been essential to the development of knowledge in the field of congenital heart disease. In many cases it gives an accurate indication of the lesions present

FIG. 252-1. A. Pure pulmonic stenosis, with prominent poststenotic dilatation of the pulmonary artery, in a 42-year-old woman. Pulmonary vascular markings in the peripheral lung fields are less prominent than normal.

B. Tetralogy of Fallot in a girl 17 years of age. Greatly increased transverse diameter, with apex of the heart "tipped up," and relatively avascular lung fields. (The three small radiopaque shadows at the upper margin of the film are artefacts.) In many cases the heart size is normal.

C. Anomalous drainage of all pulmonary veins into the left brachiocephalic (innominate) vein, with typical "figure-8" contour, in a 4-year-old boy.

D. Complete transposition of the great vessels in a 12-year-old boy. Note absence of normal pulmonary conus, with narrowing of upper mediastinal shadow in this view, prominent pulmonary vascular markings, and ventricular enlargement.

and a quantitative estimate of their functional significance.

In general, three questions can be answered by cardiac catheterization:

1. Are the pressures and pressure gradients in the heart and vessels normal? The most important

deviations from normal pressure relationships to be recognized are elevation of right ventricular or pulmonary artery pressure, or an exaggerated pressure drop across a valve, indicating stenosis.

2. Is highly oxygenated blood admixed with systemic venous blood at any point? The finding of

blood which is more highly oxygenated than samples taken further upstream (a "step-up" in oxygen saturation) may indicate a left-to-right shunt through a defect, but interpretation of such measurements is sometimes difficult. As a result of incomplete mixing of the incoming streams from the superior and inferior venae cavae and from the coronary sinus, which normally has a very low oxygen content, there is a normal variation between samples from the same chamber. In the right atrium samples may differ normally by as much as 20 ml per liter (or 2 vol per cent), in the right ventricle by less than 10 ml per liter, in the pulmonary artery by less than 5 ml per liter. Differences of larger magnitude usually indicate a left-to-right shunt, and their significance is increased if confirmed by multiple samples. It follows that small left-to-right shunts amounting to less than 15 per cent of systemic blood flow will not ordinarily be detected by their effect on blood oxygen content. Right heart catheterization will not identify the site of a right-to-left shunt unless the catheter passes through a defect or indicator-dilution curves are employed.

3 Does the catheter follow an abnormal course or pass through an abnormal opening? Under the fluoroscope the catheter may sometimes pass through a congenital defect and thus provide *prima facie* evidence of an anomalous communication. Such observations must, however, be interpreted cautiously, for the fluoroscopic image of the catheter in a single plane does not always identify its anatomic location unequivocally. Moreover, it is not always possible to put the catheter where one wants it. In occasional patients, for example, repeated attempts to advance the catheter into the pulmonary artery will fail, even in the absence of pulmonary stenosis or other abnormality. Failure to pass the catheter through a suspected defect is therefore of *limited significance*.

Catheterization studies are usually done with the patient at rest, under conditions approaching as nearly as possible a steady basal state. Alterations in this steady state during the procedure, which may change the relative oxygen saturation of consecutive blood samples, are to be avoided.

In many cases, a reliable diagnosis can be reached on the basis of history, physical examination, and roentgenographic and electrocardiographic studies, and cardiac catheterization is not needed. Unnecessary catheterization is obviously to be avoided, although the risk is small. In large diagnostic laboratories the average mortality in cardiac catheterization is approximately 0.05 per cent. The risk in acyanotic patients with moderate symptoms is distinctly less than this figure, and most of the fatalities occur in severely ill patients with pulmonary hypertension and cyanosis. The procedure is

particularly hazardous in patients with primary pulmonary hypertension.

Cardiac catheterization is indicated when data so obtained are essential to the management of the patient, as, for example, in deciding on surgical treatment. One hesitates to use cardiac catheterization when the diagnosis is already reasonably clear from routine examination and surgery seems not indicated, but if the diagnosis is uncertain, it is better to secure the additional information provided by cardiac catheterization than to deprive a patient of possible surgical benefit. With more malformations being added constantly to the list of those amenable to surgery, it becomes increasingly important to identify the lesions in each case of congenital heart disease, by catheterization or other appropriate methods. Table 252-1 lists typical data obtained by cardiac catheterization in some of the more common congenital anomalies.

Catheterization of the chambers of the left heart can be carried out by a number of different routes. It is most widely used to evaluate acquired abnormalities of the mitral or aortic valve, but in congenital disease combined right and left heart catheterization can be used to localize left-to-right shunts and to obtain the measurements needed to estimate pulmonary vascular resistance.

Pressure measurements by direct puncture during open thoracotomy are now routine in many surgical departments and can give valuable data concerning the lesion and the immediate results of surgery. It should be emphasized, however, that measurements obtained in the presence of the relatively low cardiac output, systemic pressure, and pulmonary artery pressure of the anesthetized patient with an open chest may be radically different from those under more normal conditions.

Indicator-dilution Curves. Rapid injection of a small amount of dye or other indicator into one of the chambers of the heart is followed by a characteristic arterial time-concentration curve in the normal circulation (Fig. 252-2). A shunt that permits the indicator to reach the artery prematurely superimposes an early curve on the normal one, while a shunt that delays some portion of the indicator gives a typically low, prolonged curve. Successive injections in the venae cavae and right heart chambers can identify the site of a right-to-left shunt, since injections distal to the shunt will produce normal arterial curves, while injections proximal to the shunt demonstrate the premature arrival of indicator that travels through the shunt. Very small shunts can be detected by this method under optimal conditions, and a rough estimate of the shunt flow can be made from the resulting curves.

Numerous diagnostic tests employing this principle have been devised. By varying the site of

Table 252-1. TYPICAL HEMODYNAMIC MEASUREMENTS IN SOME CONGENITAL CARDIOVASCULAR MALFORMATIONS

Measurements	Normal	Atrial septal defect	Ventricular septal defect	Patent ductus arteriosus	Ventricular septal defect with pulmonary hypertension	Tetralogy of Fallot	Pulmonary stenosis (valvular)

Shunt L to R	0	11.1	3.9	3.6	2.4	0.4	0
Shunt R to L	0	0.3	0.3	0	1.0	1.2	0
Pulmonary vascular resistance, R.U./m ²	1.0	0.8	1.5	1.5	16.4	1.9	2.0

The values given represent typical patients but individual cases differ widely. Mean pressure in the left atrium is assumed to be 6.0 mm Hg and pulmonary venous oxygen saturation 95 per cent. Mean pressures and oxygen saturation are listed in parentheses.

Symbols

VC = average of superior and inferior vena cava samples, RA = right atrium, RV = right ventricle; PA = pulmonary artery, FA = femoral artery; R.U. = resistance units, in mm Hg/liter/min; multiply by 80 to convert to dyne/cm².

infection, and sampling from catheters in the heart as well as the peripheral artery, the site, direction, and approximate magnitude of most shunts can be accurately determined. Radioactive materials, inhaled gases, and substances that alter the electrical resistance or redox potential of the blood can be used as indicators, as well as nontoxic dyes. One or more of the available techniques should be available in any catheterization laboratory concerned with the diagnosis of congenital heart disease.

Phonocardiography. The graphic recording of heart sounds and murmurs has clarified the interpretation of a number of auscultatory phenomena and made possible a more intelligent use of the stethoscope. In practice, however, it is rarely necessary to record the phonocardiogram except when the precise timing of an extra sound or the duration of a murmur is in question.

COMPLICATIONS

In many types of congenital heart disease there appears to be a lowering of resistance to infections in general and to respiratory infections in particular. A history of repeated attacks of bronchitis or pneumonia is common, particularly in children and particularly with atrial septal defect. In at least some cases malnutrition and underdevelopment may be ascribed to these recurrent illnesses. Neither hypogammaglobulinemia nor deficient antibody for-

mation seems to be concerned in this lowered resistance.

Bacterial endocarditis, acute or subacute, is a common complication of congenital heart disease. About 10 per cent of all cases of subacute bacterial endocarditis occur in congenital heart disease. Patent ductus arteriosus, ventricular septal defect, coarctation of the aorta, and bicuspid aortic valve are

FIG. 252-2. Schematic representation of arterial indicator-dilution curve after injection of dye into right atrium, normal circulation (—); left-to-right shunt (---); right-to-left shunt (....). Injections at other sites would be needed to determine whether the shunt were between the right and left atrium, the right and left ventricle, or the pulmonary artery and aorta.

under the age of thirty years, even in the absence of symptoms.

Patients with congenital malformations of the heart and symptoms which unmistakably limit their activity or in whom there are signs of cardiac embarrassment or symptoms of increasing severity should be carefully studied as possible candidates for surgery. The risk of correction with open-heart surgery has steadily diminished since Gibbon began the use of the pump oxygenator in 1953, and correction is possible with an operative mortality of no more than several per cent.

In estimating the severity of the burden imposed on the heart, the patient's response to such ordinary activities as walking and climbing stairs is a good guide. Dyspnea is a subjective phenomenon, however, and the patient's own estimate of his limitations may be misleading in either direction. An objective test of myocardial competence in relation to ordinary activity is badly needed. Measurement of cardiac output, shunts, and intracardiac pressure, particularly under resting conditions, does not sufficiently answer this need.

In cases with severe and prolonged pulmonary hypertension, the decision to operate is particularly difficult. In many patients, but not all, pulmonary hypertension appears to be reversible when a right-to-left shunt is corrected early in life. There is less likelihood of complete reversibility if the increased pulmonary flow has persisted for a long period or if the pulmonary vascular resistance is greatly increased. In the advanced states the shunt may reverse, producing cyanosis and a larger systemic than pulmonary flow. Unless there is reversal of the shunt, correction of the defect should be theoretically beneficial, but patients with advanced pulmonary vascular changes may not withstand the stress of operation. In brief, unless there is evidence of a significant left-to-right shunt, there is little likelihood of benefit from the operative procedure unless the patient is a young child.

SPECIFIC MALFORMATIONS

Congenital heart disease includes such a variety of anatomic lesions and so many possible combinations of lesions that some system of classification is essential. Either structural or functional abnormalities can be used as a basis for such classification, but it is difficult to reconcile the two in a single system. Most cases of ventricular septal defect with pulmonic stenosis are cyanotic, for example, and most cases of atrial septal defect are not, but exceptions are too frequent to be ignored. The classification introduced by Maude Abbott, a pioneer in this field, depends primarily on the presence or

absence of cyanosis; yet this sign is found with many lesions that have little else in common.

The compromise adopted in the section that follows is to group congenital anomalies under three major headings according to their effect on blood flow:

1. Malformations that permit shunting of blood
 - a. Initial shunt left to right
 - b. Initial shunt right to left
2. Malformations that obstruct blood flow
3. Malformations with no direct effect on blood flow

Malformations with Potential Shunts

Initial Left-to-Right Shunt

Atrial Septal Defect. This is the most common congenital lesion of the heart. The defects may be single or multiple and vary in size from an open foramen ovale to complete absence of the interatrial septum (cor triloculare biventriculare). Patency of the foramen ovale with an unsealed valve, which persists in 5 to 20 per cent of the adult population, does not usually permit shunting of blood, since the valve flap over the foramen prevents left-to-right flow and is held closed as long as atrial pressures remain normal.

Atrial septal defects may be divided into two general types: *persistent ostium secundum* (cephalad or midseptal in location) and *persistent ostium primum* (caudad, with one margin of the opening made up by the tissue between the atrioventricular valves). This distinction has a practical value for the surgeon, since the persistent ostium primum is technically much more difficult to repair. It also serves a clinical purpose in that the ostium primum type of defect, also called atrioventricular canal or endocardial cushion defect, is often accompanied by persistence of the atrioventricular cleft in the mitral and tricuspid leaflets, which may cause clinically recognizable insufficiency of one valve or of both.

Ostium Secundum Defects. The shunt through an atrial septal defect is predominantly from left to right, presumably because left atrial pressure is normally slightly higher than right atrial pressure and because the right ventricle presents less resistance to diastolic filling than the left. Pulmonary blood flow is usually two or three times the systemic blood flow. At the same time, streamlining of flow often produces a small right-to-left shunt, which lowers systemic arterial oxygen saturation slightly. Marked arterial unsaturation does not appear unless complications such as pulmonic stenosis or increased pulmonary vascular resistance are present.

the lesions most likely to become infected, while patients with atrial septal defect rarely develop this complication. It may appear at any age but is commonest in young adults. The symptoms, signs, and treatment of subacute bacterial endocarditis are the same with congenital heart disease as with other cardiac abnormalities. Subacute bacterial endocarditis in patent ductus arteriosus is in itself an indication for surgical closure, and this procedure alone will usually terminate the infection.

Because of the susceptibility of many congenital cardiovascular malformations to bacterial endocarditis, prophylactic antibiotic treatment should be carried out during procedures which may produce transient bacteremia, such as dental extractions. Continuous prophylaxis similar to that employed in rheumatic heart disease is not indicated, however.

Thromboses are common, particularly in the cerebral circulation. The high incidence in polycythemic patients, and after dehydration, suggests a relationship with blood viscosity. Fluid intake should be carefully watched in such patients, particularly in warm weather. Cerebral thromboses may present with convulsions or sudden hemiplegia, or they may be immediately fatal. Treatment of the polycythemic patient is based on use of anticoagulant drugs, venesection, and hemodilution with intravenous isotonic fluids.

Brain abscess is a serious complication of congenital heart disease which may appear any time after the first year or two of life. It is more frequent in patients with right-to-left shunts, since bacterial emboli bypass the lung filter and enter the brain. Successful treatment depends largely on early diagnosis, and the possibility of brain abscess should be considered promptly in any patient with congenital heart disease who develops unexplained fever, headaches, or other appropriate signs or symptoms.

THERAPY

Medical. Medical treatment of congenital heart disease consists mainly in the treatment of heart failure, maintenance of myocardial compensation, and prevention and treatment of complications.

Many cases of congenital heart disease are instances of "high-output failure" (see Chap. 13), in the sense that at least one ventricle is required to pump more than its normal output per minute. Digitalis is nevertheless just as effective in these cases as in the "low-output failure" of most forms of acquired heart disease.

The congestive heart failure which occurs with congenital malformations of the heart does not differ essentially from that seen in other diseases of the heart, and the principles of treatment are similar. Right ventricular failure is more common than

left in congenital heart disease, and is usually a more chronic problem.

Digitalis is the keystone of therapy for establishing and maintaining cardiac compensation. The choice of a digitalis preparation is dictated by the speed of action required and the personal prejudices of the individual physician. There is no convincing evidence to show that the numerous digitalis preparations available differ in their clinical effects except in rapidity and duration of action.

In the polycythemic patient venesection serves a double purpose by decreasing blood viscosity as well as temporarily reducing total blood volume, but it must nevertheless be used cautiously.

Surgical. The list of congenital abnormalities which can be corrected or relieved by surgery is constantly growing, but the more common abnormalities which can at present be successfully treated include: patent ductus arteriosus, pulmonary valvular or infundibular stenosis (either isolated or in the tetralogy of Fallot), coarctation of the aorta, atrial septal defect, anomalous pulmonary venous drainage, aortic stenosis, ventricular septal defect, transposition of the great vessels, and congenital stenosis of the mitral and tricuspid valves. These anomalies are enumerated in approximately the order of increasing operative risk, which varies widely with the different lesions. Closure of patent ductus arteriosus, for example, has been carried out in hundreds of patients since 1939, and the present operative mortality is about 2 per cent, while open-heart surgery on transposition of the great vessels has been successful for only a short time, and complete evaluation of the risk and the results is not yet possible.

The responsibility of deciding whether surgery is to be advised in the individual case should be shared by the internist and the surgeon. The only rational basis for such a decision is accurate knowledge of the prognosis without operation in the case in question, as compared with the risk and chance of benefit from surgery. Under many conditions the factors which enter into this comparison are not completely known.

In general, patients with physical signs of congenital heart disease but without symptoms clearly related to their heart disease or signs of cardiac embarrassment should not undergo corrective surgery as prophylaxis against future difficulty. There are at least three exceptions to this generalization: patent ductus arteriosus, coarctation of the aorta, and atrial septal defect. The chances of subacute bacterial endocarditis, increasing difficulty with advancing age, or other possibly fatal complications are great enough with these three lesions and the risk of operation low enough that surgical correction should be considered in all affected patients

The clinical effects of an atrial septal defect depend primarily on the size of the defect and the volume of the shunt through it. A small proportion of cases remain asymptomatic throughout adult life. In patients who develop symptoms, the earliest complaints are exertional dyspnea and fatigue. Paroxysmal atrial tachycardia with varying degrees of block is a frequent manifestation. Growth and development are essentially normal unless there is an unusually large shunt, and the "gracile habitus" shown by some children is relatively rare. Cyanosis and evidence of pulmonary hypertension are not encountered until late in the disease, if at all.

A systolic murmur in the second left intercostal space is the most prominent and constant physical finding. It begins early in systole, reaches a maximal intensity in midsystole, and diminishes rapidly to terminate before the pulmonic second sound, characteristics which suggest that it arises from ejection of a large stroke volume into the dilated pulmonary artery (p. 1411).

The aortic and pulmonic components of the second sound are clearly separated so that the second sound in the pulmonic area is split, and this splitting varies little if at all with respiration. In normal persons the second sound splits appreciably only on inspiration (p. 1408).

Fluoroscopy shows a greatly enlarged pulmonary conus and pulmonary arteries, increased pulmonary vascularity, a "hilar dance," and enlargement of the right atrium and right ventricle. The electrocardiogram shows signs of right ventricular hypertrophy in almost all symptomatic cases. It has frequently been stated that the electrocardiogram in this malformation usually shows right bundle branch block, but it is more accurate to say that an rsR' pattern is often found in VI and other right precordial leads, usually with a QRS duration less than 0.12 sec. This rsR' pattern in itself is probably an indication of right ventricular hypertrophy. Paroxysmal atrial tachycardia, atrial fibrillation, and prolongation of the P-R interval are all common.

Ostium Primum Defects. When this lesion is present symptoms almost always appear in childhood, and an apical systolic murmur, plus radiologic and electrocardiographic signs of left ventricular hypertrophy as well as right suggest the diagnosis. Signs of free mitral or tricuspid insufficiency also favor the diagnosis of persistent ostium primum.

Cardiac catheterization will usually establish the diagnosis, subject to the general limitations of this procedure discussed above. The differential diagnosis between atrial septal defect and anomalous pulmonary veins draining into the right atrium is often impossible.

The majority of atrial septal defects are not complicated by other congenital lesions, except for the

tricuspid and mitral valve deformities mentioned. The combination of atrial septal defect and mitral stenosis (Lutembacher's syndrome) appears to be much less common than previously supposed. Modern diagnostic methods and surgical exploration have shown that an apical diastolic murmur is often present in cases of atrial septal defect when the mitral valve is entirely normal, and the diagnosis of Lutembacher's syndrome should therefore be made with considerable caution.

Ventricular Septal Defect. This is the second most frequent congenital anomaly of the heart. More than 90 per cent are defects of the membranous portion of the septum, the remainder being in the muscular portion and usually unaccompanied by other cardiac malformations. They vary in size from very small ventricular defects, which produce a loud systolic murmur but no symptoms throughout adult life (*maladie de Roger*), to complete absence of the interventricular septum (*single ventricle, cor triloculare biatriatum*).

The direction and magnitude of the shunt depend on the size of the defect and on the relative resistances to pulmonic systemic flow. In the majority of cases the shunt is predominantly from left to right, but the development of increasing pulmonary vascular resistance can reverse the direction. Patients with extremely large defects or complete absence of the interventricular septum (*single ventricle*) usually have increased pulmonary vascular resistance from birth.

A harsh systolic murmur, of greatest intensity in the third and fourth interspaces just left of the sternal edge, is the classic sign of ventricular septal defect, in the majority of cases it is accompanied by a thrill. It usually extends throughout systole (p. 1411) and is maximal in mid- or late systole. If the pressure gradient between the two ventricles decreases as pulmonary hypertension develops, the systolic murmur decreases in intensity as the pulmonic second sound increases. An apical diastolic murmur is present in most cases with large shunts, because of either relative mitral stenosis or pulmonary insufficiency (p. 1412, Chap. 251).

As long as the left-to-right shunt predominates, the roentgenogram shows increased pulmonary vascularity, and the electrocardiogram reflects combined ventricular hypertrophy. If the pulmonary vascular resistance increases markedly, the peripheral lung fields become relatively avascular, in contrast to the dilated main branches of the pulmonary artery, and signs of right ventricular hypertrophy predominate in the electrocardiogram.

Stenosis of the pulmonary valve or infundibulum may give a murmur similar to that of ventricular septal defect, but it is usually loudest in the second or third interspace, particularly with valvular stenosis. The decreased pulmonary vascularity seen by

x-ray is the most important point in distinguishing these lesions from pure ventricular septal defect. If phonocardiograms show that the murmur is undoubtedly pansystolic and definitely starts before ejection, then this evidence speaks strongly for interventricular defect as compared to pulmonary stenosis.

The systolic murmur of atrial septal defect is occasionally quite loud and may even produce a thrill, but it too is typically higher on the chest wall than in ventricular septal defect. Moreover, with atrial septal defect left ventricular hypertrophy does not occur unless mitral incompetence is also present. In ventricular septal defect with marked pulmonary hypertension, right ventricle enlargement predominates, and differentiation from atrial septal defect by clinical means may be impossible.

Ventricular Septal Defect in Combination with Other Lesions. Approximately 8 out of every 10 patients with an interventricular septal defect have other cardiac malformations as well, the most common being pulmonary stenosis. Aortic incompetence due to an anomalous aortic cusp is an occasional complicating lesion of considerable importance, because the murmurs and wide pulse pressure may lead to an erroneous diagnosis of patent ductus arteriosus.

Eisenmenger's complex is the name sometimes applied to a condition characterized by ventricular septal defect in which cyanosis develops in adolescence or later adult life. The aortic root is normally positioned in most cases, and the clinical course is the result of gradually increasing pulmonary vascular resistance, with increasing pulmonary hypertension and eventual reversal of the shunt.

Patent Ductus Arteriosus. The ductus arteriosus, which is an essential communication between the pulmonary artery and aorta during fetal development, normally closes before the age of two years.

Persistent patency of the ductus arteriosus beyond this age is a common abnormality, representing approximately 10 per cent of all congenital malformations seen clinically. The lumen varies from 5 to 10 mm in most patients. With the normally existing pressure gradients, there is a left-to-right shunt from the aorta to the pulmonary artery, but this varies greatly in magnitude in different patients and is often well tolerated. The majority of patients with this anomaly are asymptomatic and are unaware of its existence until it is discovered on routine physical examination.

The open ductus provides a low-resistance pathway from the aorta during diastole as well as systole, and a lowering of the arterial diastolic pressure results. The arterial pulse pressure is thereby widened, just as in aortic regurgitation.

The left ventricle bears the burden of the shunt, showing hypertrophy and enlargement in cases

where the shunt is large enough to cause symptoms. As in other left-to-right shunts, continued high pulmonary blood flow is sometimes followed by the development of pulmonary hypertension. This tends to decrease the left-to-right shunt, and if the pulmonary artery pressure reaches systemic levels, the flow through the ductus will be reversed, with cyanosis of the toes and the area of the body nourished by branches of the aorta distal to the ductus. In such cases, cyanosis may appear at first only with exertion, but if the patient survives, the right-to-left shunt becomes permanent, even at rest.

When the ductus enters the aorta distal to the great vessels of the aortic arch, as is customary, a venous-arterial shunt through it gives rise to the *almost pathognomonic finding of cyanosis of the lower extremities with normally pink upper extremities*. Once this stage has been reached the prognosis is poor, and survival for more than a few years is exceptional.

The classic machinery murmur of patency of the ductus extends through systole and diastole, as does the flow of blood through the ductus. The murmur reaches its maximal intensity about the end of systole and "overrides" the second sound, which may be completely obliterated. It may begin with the first sound or in early systole, and may extend throughout diastole, or die away in late diastole. The second left interspace at the sternal border is most often the area of maximal intensity. The systolic element may be heard over most of the precordium and above the clavicles, while the diastolic is sometimes less widely transmitted. As in other left-to-right shunts, a separate apical diastolic murmur from relative mitral stenosis is sometimes heard.

Pulmonary hypertension modifies the typical murmur just as it modifies the size and direction of the shunt. With roughly equal pressures in aorta and pulmonary artery and little or no shunt, the murmur may disappear entirely, while under other circumstances either the diastolic or the systolic component may be absent. Other causes of continuous murmurs are considered on p. 1413, Chap. 251.

Fluoroscopy may show a prominent pulmonary conus, slight right and left ventricular enlargement, slight increase in pulmonary vascularity, or no abnormality at all. The electrocardiogram may show moderate left, or combined ventricular, hypertrophy but is more often within normal limits.

Patent ductus arteriosus can occur in combination with many other malformations. In some instances, such as complete pulmonary atresia, a patent ductus performs an essential function by carrying blood to the lungs.

Differential diagnosis is relatively easy in the average patient with a typical murmur and no cyanosis. Although many other lesions produce both systolic and diastolic murmurs, the two murmurs are

usually separate and do not continue through the second sound. Defects of the septum between the ascending aorta and pulmonary artery are an exception to this rule, which is not surprising since this anomaly is physiologically identical with patent ductus, except for the slightly more proximal site of the communication. Cardiac catheterization may be of help in differentiating between patent ductus arteriosus and such aortic septal defects, if the catheter passes through the defect. Retrograde aortography may establish the diagnosis.

Anomalous Pulmonary Venous Drainage. This is a relatively uncommon malformation. The most frequent sites of drainage are the superior vena cava, the right atrium, the left innominate vein, and the coronary sinus. The effects of this malformation are determined by the proportion of the blood from the lungs that is returned to the right heart. If all pulmonary veins drain into the right heart, an associated patent foramen ovale or atrial septal defect is essential for survival. Partial anomalous drainage, in which some pulmonary veins enter the right side of the heart while others enter the left atrium normally, may occur without other complicating lesions.

Partial anomalies are often well tolerated and may be entirely asymptomatic, while total anomalous drainage is a much more severe handicap; less than a fifth of patients with the latter condition survive beyond infancy.

In both situations there is a left-to-right shunt, and therefore increased pulmonary blood flow, but the size of the shunt varies greatly. In patients with total anomalous pulmonary venous drainage, there may be a history of cyanosis at birth and infancy and mild degrees of cyanosis at rest or on exertion, and even clubbing in later life.

Physical signs may be lacking in cases of partial anomalous pulmonary venous drainage, but in the total anomalies there is almost always a grade 2 to 4 systolic murmur, often with a thrill, in the second to fourth intercostal space at the left sternal border. This is probably related to an associated atrial septal defect and the accompanying dilatation of the pulmonary artery. A softer, continuous murmur is often heard in the aortic area, probably a true "venous hum" from increased flow through the anomalous veins.

Roentgenograms may be characteristic in three specific patterns of anomalous pulmonary venous drainage: (1) a common right pulmonary vein draining into the inferior vena cava, which adds a smooth semicircular shadow to the right heart border; (2) total pulmonary venous drainage into a persistent left superior vena cava, giving a "figure-8" or "snowman" contour to the whole cardiovascular silhouette (Fig. 252-1C); (3) total pulmonary venous drainage into the coronary sinus, in which

the greatly dilated coronary sinus and anomalous veins displace the esophagus posteriorly, simulating left atrial enlargement. The electrocardiographic findings are normal in most asymptomatic patients and show signs of right ventricular hypertrophy as symptoms become predominant.

Hemodynamically, the systemic flow is normal or slightly lowered, while the left-to-right shunt gives an increased pulmonary flow varying from one and one-half to five or more times the systemic flow. Peripheral arterial oxygen saturation may be normal with partial anomalies, but with totally anomalous drainage the pulmonary and systemic venous blood are mixed in the right atrium, and pulmonary arterial and aortic blood are equally unsaturated. Pulmonary artery pressure is usually normal or slightly elevated.

Cardiac catheterization can demonstrate the left-to-right shunt and "step-up" in oxygen saturation in the right atrial blood but cannot distinguish between anomalous pulmonary venous drainage into the right atrium and atrial septal defect unless the catheter actually passes out one of the pulmonary veins from the vena cava or the right atrium. Even this finding is often equivocal, since it is difficult to be sure that the catheter has not passed into normally draining pulmonary veins by way of an atrial septal defect. The situation is further complicated by the frequent association of the two anomalies. Angiocardiography can be helpful in demonstrating anomalous pulmonary veins draining into the venae cavae or coronary sinus, but it does not rule out concomitant atrial septal defect. In many cases, therefore, differential diagnosis of these two malformations can be made only at thoracotomy.

When the anomalous veins drain only one lung, a specialized application of the dye-dilution method may establish the diagnosis. Injection of dye or other indicator into first one and then the other main branch of the pulmonary artery will give a normal dilution curve in the systemic arteries after injection into the normally drained lung and a curve typical of a left-to-right shunt after injection into the anomalously drained pulmonary bed.

As has been indicated, many patients with partial anomalous pulmonary venous drainage are without symptoms, and therapy is not needed. In others, however, and particularly in the total anomalies, signs of right heart failure develop because of a large shunt or pulmonary hypertension, or both. In these patients surgical intervention should be considered, although with total anomalies and with marked pulmonary hypertension, the risk of operation is high.

Initial Right-to-Left Shunt

These are the cases of "cyanotic heart disease" in which the malformed structure of the heart and

great vessels diverts all or part of the right ventricular output into the aorta from birth, so that the fetal predominance of the right ventricle persists.

The partitioning of the embryonic truncus arteriosus into pulmonic and aortic channels is a key stage in the development of the heart, and anomalies in this process underlie a number of clinical malformations, including complete transposition of the great vessels, Fallot's tetralogy, and some defects of the membranous portion of the interventricular septum. An understanding of this episode in the development of the human fetus is essential to a logical appreciation of these lesions, and the excellent reviews of Harris and Farber and Patten are recommended.

Deviations in the location of the partitioning septum can produce great variations in the relative size of the aorta and pulmonary artery. Failure of the normal twisting of the truncus may leave the aorta in direct communication with the right ventricle only, and the pulmonary artery with the left ventricle, as in complete transposition. The almost unlimited permutations and combinations of such developmental errors can lead to the most complex malformations. The caudad end of the truncus septum is contiguous with the membranous portion of the interventricular septum and with the edge of the interatrial septum which closes the ostium primum. Any abnormality of development in this relatively small area in the fetus can give rise to such apparently diverse anomalies as transposed great vessels, defects of the interatrial and interventricular septum, and anomalies of the atrioventricular valves.

Transposition of the Great Vessels. In this malformation the failure of normal torsion of the primitive truncus leaves the aortic root opening into the right ventricle and the pulmonary artery into the left. This separation of the pulmonic and systemic circulation into two independent circuits is obviously incompatible with life unless some additional anomaly provides a communication between them. Complete transposition of aorta and pulmonary artery is, therefore, not seen clinically except in combination with other anomalies such as patent foramen ovale, atrial septal defect, ventricular septal defect, or patent ductus arteriosus. The bronchial arteries provide an additional shunt pathway in many cases. The larger the communication, the better the patient's chances for survival.

In patients with these conditions the paths of blood flow are not yet fully understood, but they involve mixed shunts which may reverse their direction from systole to diastole. There is usually marked lowering of peripheral arterial saturation, with cyanosis and polycythemia.

Signs and symptoms, including cyanosis, are present from birth, and rapid cardiac enlargement

during the first year of life is the rule. The malformation is occasionally seen in older children, but the majority of the infants affected die during the first year, unless compensating anomalies coexist.

A precordial bulge is frequently present, owing to the early cardiac enlargement, and the precordial pulsation is indicative of dominant right ventricular enlargement. The second pulmonic sound is greatly accentuated and not split. Systolic murmurs and thrills are usually found but are related to the associated defects rather than to the transposition itself. Some patients with a patent foramen ovale or patent ductus arteriosus have only faint systolic murmurs or none at all.

The radiologic picture is often characteristic (see Fig. 252-1D).

When the ascending aorta lies directly ventral to the pulmonary trunk, their shadows are superimposed, giving an unusually narrow upper mediastinal shadow and an absence of the usual pulmonary conus. The pulmonary arteries and smaller vessels are large and pulsate vigorously. Both ventricles, and often both atria, are enlarged. Right axis deviation and marked right ventricular hypertrophy are found in the electrocardiogram.

The diagnosis can usually be made from the history and roentgenologic features. On cardiac catheterization the catheter may enter the aorta, and the characteristically anterior origin of the aorta may be identified in the lateral view.

Surgical creation of an atrial septal defect may help patients with this condition by allowing greater mixing of pulmonary and systemic blood. More complete correction has been possible in a few instances with open-heart surgery, the most successful operations being directed at producing transposition of the pulmonary veins and venae cavae to correct for the transposed great arteries. The operation is better done in infants before pulmonary vascular changes become excessive.

A variant of this anomaly is complete transposition of the aorta with only partial transposition of the pulmonary artery, so that the pulmonary artery overrides the right ventricle, and a high ventricular septal defect (Taussig-Bing complex). Although this malformation differs developmentally from the Eisenmenger complex, the clinical pictures are similar. The single distinguishing feature is the appearance of cyanosis at birth in the Taussig-Bing complex, as contrasted with its later appearance in the Eisenmenger complex.

Persistent Truncus Arteriosus. This is a rare anomaly in which blood flows from both ventricles into a single common trunk overriding a high ventricular ventral defect. Blood reaches the lungs through pulmonary arteries branching from this trunk. There may be a right or left aortic arch.

Cyanosis is present, but its degree depends on

usually separate and do not continue through the second sound. Defects of the septum between the ascending aorta and pulmonary artery are an exception to this rule, which is not surprising since this anomaly is physiologically identical with patent ductus, except for the slightly more proximal site of the communication. Cardiac catheterization may be of help in differentiating between patent ductus arteriosus and such aortic septal defects, if the catheter passes through the defect. Retrograde aortography may establish the diagnosis.

Anomalous Pulmonary Venous Drainage. This is a relatively uncommon malformation. The most frequent sites of drainage are the superior vena cava, the right atrium, the left innominate vein, and the coronary sinus. The effects of this malformation are determined by the proportion of the blood from the lungs that is returned to the right heart. If all pulmonary veins drain into the right heart, an associated patent foramen ovale or atrial septal defect is essential for survival. Partial anomalous drainage, in which some pulmonary veins enter the right side of the heart while others enter the left atrium normally, may occur without other complicating lesions.

Partial anomalies are often well tolerated and may be entirely asymptomatic, while total anomalous drainage is a much more severe handicap; less than a fifth of patients with the latter condition survive beyond infancy.

In both situations there is a left-to-right shunt, and therefore increased pulmonary blood flow, but the size of the shunt varies greatly. In patients with total anomalous pulmonary venous drainage, there may be a history of cyanosis at birth and infancy and mild degrees of cyanosis at rest or on exertion, and even clubbing in later life.

Physical signs may be lacking in cases of partial anomalous pulmonary venous drainage, but in the total anomalies there is almost always a grade 2 to 4 systolic murmur, often with a thrill, in the second to fourth intercostal space at the left sternal border. This is probably related to an associated atrial septal defect and the accompanying dilatation of the pulmonary artery. A softer, continuous murmur is often heard in the aortic area, probably a true "venous hum" from increased flow through the anomalous veins.

Roentgenograms may be characteristic in three specific patterns of anomalous pulmonary venous drainage: (1) a common right pulmonary vein draining into the inferior vena cava, which adds a smooth semicircular shadow to the right heart border; (2) total pulmonary venous drainage into a persistent left superior vena cava, giving a "figure-8" or "snowman" contour to the whole cardiovascular silhouette (Fig. 252-1C); (3) total pulmonary venous drainage into the coronary sinus, in which

the greatly dilated coronary sinus and anomalous veins displace the esophagus posteriorly, simulating left atrial enlargement. The electrocardiographic findings are normal in most asymptomatic patients and show signs of right ventricular hypertrophy as symptoms become predominant.

Hemodynamically, the systemic flow is normal or slightly lowered, while the left-to-right shunt gives an increased pulmonary flow varying from one and one-half to five or more times the systemic flow. Peripheral arterial oxygen saturation may be normal with partial anomalies, but with totally anomalous drainage the pulmonic and systemic venous blood are mixed in the right atrium, and pulmonary arterial and aortic blood are equally unsaturated. Pulmonary artery pressure is usually normal or slightly elevated.

Cardiac catheterization can demonstrate the left-to-right shunt and "step-up" in oxygen saturation in the right atrial blood but cannot distinguish between anomalous pulmonary venous drainage into the right atrium and atrial septal defect unless the catheter actually passes out one of the pulmonary veins from the vena cava or the right atrium. Even this finding is often equivocal, since it is difficult to be sure that the catheter has not passed into normally draining pulmonary veins by way of an atrial septal defect. The situation is further complicated by the frequent association of the two anomalies. Angiocardiography can be helpful in demonstrating anomalous pulmonary veins draining into the venae cavae or coronary sinus, but it does not rule out concomitant atrial septal defect. In many cases, therefore, differential diagnosis of these two malformations can be made only at thoracotomy.

When the anomalous veins drain only one lung, a specialized application of the dye-dilution method may establish the diagnosis. Injection of dye or other indicator into first one and then the other main branch of the pulmonary artery will give a normal dilution curve in the systemic arteries after injection into the normally drained lung and a curve typical of a left-to-right shunt after injection into the anomalously drained pulmonary bed.

As has been indicated, many patients with partial anomalous pulmonary venous drainage are without symptoms, and therapy is not needed. In others, however, and particularly in the total anomalies, signs of right heart failure develop because of a large shunt or pulmonary hypertension, or both. In these patients surgical intervention should be considered, although with total anomalies and with marked pulmonary hypertension, the risk of operation is high.

Initial Right-to-Left Shunt

These are the cases of "cyanotic heart disease" in which the malformed structure of the heart and

lesions. Cases of valvular stenosis with normal ventricular septum are relatively common and may constitute as much as 10 per cent of all patients with congenital heart disease. The degree of stenosis varies from slight narrowing to a domelike membrane with only a pinhole opening.

The principal effects of this lesion are reduction of the pulmonary blood flow and right ventricular hypertension and hypertrophy. When the right ventricle can no longer maintain the high pressure needed to propel blood through the lungs, congestive failure supervenes, with the increased peripheral venous pressure, hepatic distention, and peripheral edema characteristic of right ventricular failure.

Shunts are not usually present in the early course of the disease or in mild cases, but right-to-left shunts may develop through an unsealed foramen ovale or concomitant atrial septal defect if right atrial pressure eventually rises.

Patients with mild degrees of pulmonary stenosis may have no symptoms and have an excellent prognosis. In more severe cases, the age of onset of symptoms—primarily exertional dyspnea or syncope—varies widely, but in the average case is during adolescence. Exertional dyspnea usually precedes the appearance of cyanosis and for some time is more striking than the cyanosis. Once cyanosis has appeared symptoms gradually become more severe, but there are striking exceptions to this rule, and occasional patients continue to exhibit cyanosis on exertion for 20 years or more, with little change. Clubbing is present in proportion to the severity and duration of cyanosis.

The most important physical signs of pulmonic stenosis are a systolic murmur with maximal intensity (usually at least grade 4) in the pulmonic area and a diminished or absent second pulmonic sound. Phonocardiograms reveal a splitting of the second sound, but only the first (or aortic) component may be audible. With infundibular stenosis the site of greatest intensity is somewhat lower, in the third to fourth interspace at the left sternal border. The murmur terminates before the second pulmonic sound. Diastolic murmurs are not usually present, a point which is helpful in differentiating this lesion from ventricular septal defect. Signs of right ventricular failure, including enlargement and sometimes pulsation of the liver, develop in the most severe instances.

Radiographic study shows a prominence or actual enlargement of the pulmonary artery and its main branches, the so-called "poststenotic dilatation" (see Fig. 252-1), with valvular stenosis but usually not with infundibular stenosis. The pulmonary arteries do not pulsate actively as a rule, but with mild stenosis slight pulsation may occur. The vascularity of the lungs is diminished, giving a relatively clear

appearance to the peripheral lung fields. In mild cases the ventricles are of normal size, while in severe cases the right ventricle may be enormously enlarged. The right atrium usually enlarges along with the right ventricle.

Electrocardiographic signs of right ventricular hypertrophy are roughly proportional to the degree of obstruction. Severe degrees of pulmonic stenosis produce the greatest increase in the amplitude of the R wave over the right precordium (up to 4.0 mv) encountered clinically. Right atrial enlargement is indicated by increased P-wave amplitude, most prominently in leads II and V₁.

The most important hemodynamic finding is an increase in right ventricular pressure and the demonstration of a large pressure gradient across the site of the stenosis. Right ventricular systolic pressure in symptomatic patients is usually between 60 and 180 mm Hg, but one patient with a pressure of 270 mm Hg has been reported. The pressure drop across the stenosis is often 100 mm Hg, or more. The systemic flow is usually slightly below normal, but not so much below as one would expect from the severity of symptoms. One critical handicap in patients with this condition is their limited ability to increase pulmonary flow on exercise, even with considerable increase in right ventricular pressure. In extreme instances, exertion may lead to syncope.

Cases showing early cyanosis must be differentiated from tetralogy of Fallot, and those with late onset of cyanosis from Eisenmenger's complex. A prominent pulmonary artery, enlarged heart and right atrium, and marked dyspnea with relatively little cyanosis help to rule out tetralogy of Fallot, while clear lung fields and absence of pulmonary artery pulsation are not usually found in Eisenmenger's complex. Cardiac catheterization can furnish direct evidence of the stenosis and the degree of right ventricular hypertension. Accurate diagnosis is of particular importance because the Blalock-Taussig operation does not benefit patients with isolated pulmonic stenosis, the increased left-to-right shunt apparently being the last straw for an already overburdened right ventricle, which rapidly fails. A specific attack on the pulmonic stenosis is the treatment of choice.

Other malformations may be found in combination with pulmonic stenosis, including anomalous pulmonary veins, atrial or ventricular septal defects, and patent ductus arteriosus.

The prognosis is good in uncomplicated cases without cyanosis, cardiac enlargement, or electrocardiographic signs of right ventricular hypertrophy. When any of these findings is present, with severe or increasing symptoms, surgical relief of the stenosis should be considered. In borderline cases, the right ventricular systolic pressure is a useful

the relative proportions of pulmonary blood flow and venous-arterial shunt. Pulmonary blood flow exceeds normal values if there is free communication from the truncus to the lungs and no pulmonary vascular changes occur. This increased pulmonary blood flow, mixing with the systemic venous return, often results in an almost normal oxygen content of arterial blood, in spite of a large right-to-left shunt. The pulmonary arteries may be large, in which case pulmonary blood flow is apt to be high and cyanosis minimal early in life. At the other extreme there may be no connection of pulmonary arteries with the truncus, so that the bronchial arteries may provide the only pathway for blood flow to the lungs. Pulmonary blood flow is low and cyanosis is intense. Anatomically, this condition more closely resembles the tetralogy of Fallot than the usual truncus arteriosus.

In infants the roentgenogram may be diagnostic, with a sharp right angle between the shelflike upper surface of the right ventricle and the aorta in the left anterior oblique view. With increasing age this disappears, and the great right ventricular enlargement and absent pulmonary conus give a picture similar to that in Fallot's tetralogy.

Tetralogy of Fallot. The structural anomalies in Fallot's "tetralogy" are actually two in number: ventricular septal defect and pulmonic stenosis. Although overriding of the aorta was originally considered an essential feature of this syndrome, defects of the membranous portion of the ventricular septum leave the aortic root in close proximity to the right ventricular outflow tract even when the aorta is in normal position, so that the anatomic and hemodynamic findings in most cases can be explained without assuming dextroposition of the aorta. The right ventricular hypertrophy that completes the tetralogy is a consequence of the functional abnormality induced by the structural lesions.

Fallot's tetralogy is the most common combination of lesions which leads to early cyanosis yet often allows survival into adult life. The stenotic obstruction is usually in the infundibulum or right ventricular outflow tract, but may be in the valve itself, or at both sites. Dilatation of the pulmonary artery beyond the stenosis is usually not striking. In some instances, there is atresia of the pulmonary artery, and blood reaches the lung through other channels, a condition sometimes confusingly referred to as "pseudotruncus arteriosus." A large right-to-left shunt is present, with cyanosis appearing either at birth or within the first two years. Clubbing and polycythemia follow at an early date. The pulmonic stenosis produces a characteristic murmur, described below, and decreased pulmonary vascularity. The electrocardiogram shows right ventricular hypertrophy. The size of the heart radiologically is usually normal, but the normal leftward

convexity of the pulmonary conus is missing. In some cases the apex of the heart is somewhat "tipped up" in the anteroposterior view (see Fig. 252-1B). A right aortic arch occurs in about 25 per cent of patients and can be seen to displace the barium-filled esophagus to the left in the anteroposterior view, and posteriorly in the left anterior oblique view.

In rare cases there may be only moderate pulmonic stenosis and a left-to-right shunt. Such cases of "atypical" or "acyanotic" tetralogy of Fallot have normal or increased pulmonary vascularity, and diagnosis is often difficult.

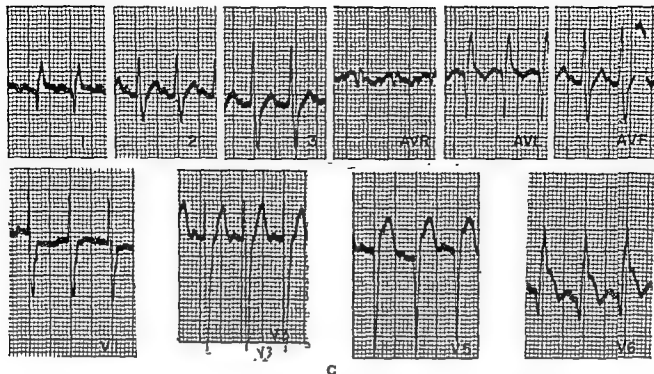

In the typical case the diagnosis can usually be made clinically. These patients are more cyanotic than the usual case of uncomplicated pulmonic stenosis and do not have the greatly enlarged heart of complete transposition of the great vessels or the enlarged, pulsating pulmonary artery of Eisenmenger's complex.

Although many patients with tetralogy of Fallot reach adult life, their exercise tolerance is invariably limited, and very few survive beyond the age of thirty years. The Blalock-Taussig operation provides an increased blood flow to the lungs through an artificial ductus, relieving the cyanosis and clubbing and greatly increasing ability to exercise.

Anomalous Origin of Coronary Arteries. This is a rare malformation in which one coronary artery, usually the left, arises from the pulmonary artery. A few cases with both coronary arteries arising from the pulmonary artery have been reported. The combination of low coronary perfusion pressure and low oxygen tension seriously impairs myocardial function. Severe congestive heart failure and cardiac enlargement appear in the first few months of life. Pulmonary and peripheral edema may both develop. The electrocardiogram shows S-T and T-wave abnormalities strikingly similar to those seen in adults with acute myocardial infarction (see Fig. 252-3). Murmurs are usually absent. Differentiation from other rare causes of early cardiac enlargement without cyanosis or murmurs, discussed later in this chapter, is based principally on the characteristic electrocardiographic changes. In several reported cases retrograde flow has been present in the vessel arising from the pulmonary artery, constituting in essence an arteriovenous fistula. In such cases ligation of the anomalous artery has given relief of the myocardial ischemia.

Malformations Which Obstruct Blood Flow

Pulmonary Stenosis. This may involve either the pulmonic valve or the pulmonary infundibulum. Since it is often associated with other anomalies, the terms *pure* and *isolated* pulmonic stenosis are often used to indicate the absence of complicating

C

cleft mitral leaflet producing mitral regurgitation. Combined right and left ventricular hypertrophy is indicated by the left axis deviation, tall R-V₁, and tall R-V₆. A double R wave is present in lead V₁, with QRS duration of 0.09 sec, and the P-R interval is prolonged. (Arrows indicate the peak of R-I and synchronous points in other leads.)

C. Electrocardiogram from an infant boy aged 4 months with anomalous origin of the left coronary artery. The prominent Q waves and S-T elevation in leads I, V₁, and V₂ are characteristic of anterior myocardial infarction.

blood from the pulmonary artery supplies the lower half of the body (through the ductus) and the toes are cyanotic, often in contrast to the fingers.

Postductal or adult coarctation is usually located immediately distal to the left subclavian artery, and a narrowed or obliterated ductus enters the segment proximal to the coarctation. Bicuspid aortic valve is present in 25 to 40 per cent of cases, but otherwise the heart is normal. In rare instances, coarctation may be in the midthoracic aorta, at the diaphragm, or even in the abdomen.

The presenting signs are hypertension in the arms proximal to the obstruction, and hypotension or absent pulses in the legs distal to it; by these signs the diagnosis is made. In the preductal type the associated intracardiac defects are prominent and incapacitating, and the clinical picture is largely determined by these defects. Patients with a postductal coarctation characteristically are troubled either early in life or a number of years later. A few infants develop cardiac failure because of the load placed upon the left ventricle, but most patients with coarctation of the aorta weather early childhood without symptoms or diagnosis. Heart failure in an infant suggests some other lesion, notably endocardial fibroelastosis, for most infants with

coarctation develop collateral circulation, and hypertension is not striking until late childhood or adulthood. Complaints rarely arise from diminished flow to the legs.

In addition to the pathognomonic pulse and pressure gradients, there are striking pulsations in the neck and supraclavicular areas. Systolic murmurs may be heard posteriorly from the coarctation or anteriorly from an abnormal aortic valve, and diastolic murmurs may arise from collateral circulation. Enlarged collateral vessels may be felt in the interscapular and subscapular areas.

Notching of the ribs is the most characteristic radiologic observation, caused by dilatation and tortuosity of intercostal arteries carrying the collateral flow. A "three sign" may be produced in roentgenograms of the left upper mediastinum by the enlarged left subclavian artery, the constriction at the coarctation, and poststenotic dilatation distal to it.

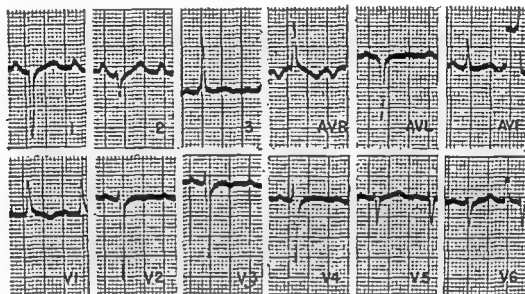

The electrocardiogram may be normal or may show left axis deviation and signs of left ventricular hypertrophy.

In addition to cardiac failure, these patients ultimately suffer cerebral accidents, rupture of the aorta, or other complications of hypertension. Un-

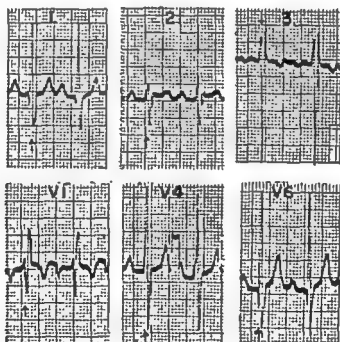

guide to prognosis, and systolic pressures greater than 100 mm Hg are usually an indication for operation.

Coarctation of the Aorta. This obstructive lesion results from an abnormal obliteration of the aorta during regression of the multiple aortic arch system of the embryo. The common classifications are based

largely upon the age at death (infantile and adult) and on the site of coarctation in relation to the ductus arteriosus. The infantile or preductal type occurs in the aortic arch or just proximal to the ductus arteriosus, which is usually patent. Commonly, there are other intracardiac defects which account for death at an early age. In most instances,

FIG. 253-3. A. Electrocardiogram from a 9-year-old girl with pure pulmonic stenosis. The right axis deviation in the limb leads, tall R wave in lead V_1 , and reversal of the normal precordial transition indicate marked right ventricular hypertrophy. Note that precordial leads were recorded at half normal sensitivity.

B. Electrocardiogram from a 5-year-old boy with an atrial septal defect ("persistent ostium primum") and

Congenital Cardiac Hypertrophy. On rare occasions, cardiac dilatation and hypertrophy, with congestive heart failure, develop during the first few months of life, in the absence of cyanosis, thrills, or murmurs. In a few of these cases no clear etiologic factors can be discovered, even on pathologic examination, and they are accurately termed *idiopathic congenital cardiac hypertrophy*.

The same clinical picture may be produced by a variety of causes, including endocardial fibroelastosis, von Gierke's disease, nonspecific myocarditis, and prolonged ectopic tachycardia.

Endocardial fibroelastosis is a collagenous and elastic tissue thickening of the endocardium lining the heart chambers, most frequently limited to the left ventricle. The etiology is not known; "fetal endocarditis" has been suggested as a possible cause, but the evidence is not convincing. In some cases the cardiac enlargement is predominantly left ventricular, while in others the endocardial sclerosis appears to constrict the left ventricle and lead to right ventricular hypertrophy.

Von Gierke's disease is a general metabolic disorder in which glycogenolysis is impaired and intracellular deposits of glycogen are found in the liver, kidneys, and myocardium. Hepatomegaly, fasting hypoglycemia, and ketonuria are characteristic features.

The diagnosis of *nonspecific myocarditis* is based on the microscopic finding of interstitial round-cell infiltration, often with small areas of necrosis or fibrosis, in the myocardium, in the absence of infectious or other known causes of myocarditis.

Prolonged paroxysms of tachycardia in infants have occasionally been reported as a cause of marked cardiac enlargement and death. Although prominent dilatation of the ventricles can occur under these circumstances, it is unlikely that myocardial hypertrophy can be attributed to a prolonged rapid heart rate alone.

253 ACQUIRED VALVULAR DISEASE OF THE HEART

T. R. Harrison and
William H. Resnik

Those congenital malformations which cause valvular deformity are discussed in Chap. 252. These include almost all instances of disease of the pulmonic cusps and rare disorders of the other three valves. However, the great majority of aortic, mitral, and tricuspid lesions are not congenital but acquired and are due to rheumatic fever. Although this disorder, which has been considered in some detail in a previous chapter (p. 913), affects all parts of the heart, its distinctive feature is calcular

less surgical correction is carried out, 51 per cent of patients with this condition die before the fortieth year, but a few survive to old age.

The pathologic physiology has been of considerable interest because hypertension in this disease is associated with a discrete lesion which can be surgically corrected. In addition to increased resistance from the constriction and the collateral vessels, a renal mechanism activated by the lowered renal blood flow and pressure seems to contribute to this hypertension.

Surgical correction is indicated in most children, and also in adults in whom hypertension is great or symptoms related to it are present. The segment can be excised and end-to-end suture performed in most instances, but in some cases a graft may be required to bridge the gap or to obtain a satisfactory lumen.

Stenosis or Atresia of Other Valves. Congenital stenosis of the mitral, tricuspid, or aortic valves is uncommon. Except for the relatively early appearance of signs and symptoms as compared with their counterparts in rheumatic heart disease, the effects are similar. *Tricuspid atresia* is usually associated with an underdeveloped or absent right ventricle, atrial septal defect, and atretic pulmonary artery. Blood flows from the right into the left atrium and left ventricle and reaches the lungs through a patent ductus arteriosus. The right ventricular cavity is absent or filled with blood clot, or it communicates with the left ventricle through a ventricular septal defect, but does not function. Left axis deviation in the electrocardiogram results, and this finding in a cyanotic patient suggests either tricuspid atresia or single ventricle.

Aortic atresia, extremely rare, is associated with a hypoplastic, nonfunctioning left ventricle, and frequently with *mitral atresia* as well. Blood flows from left atrium to right atrium to the lungs, and reaches the systemic circuit only through a patent ductus. Survival for more than a few weeks is rare. Congenital and acquired varieties of aortic stenosis, as well as the vigorous contractions of the aortic outflow tract, which mimic true stenosis are considered on p. 1434, Chap. 253).

Malformations without Direct Effect on Blood Flow

Dextrocardia and Situs Inversus. Dextrocardia may occur as an exact mirror-image reversal of the heart within the thorax (*true dextrocardia*) or as abnormal rotation of the heart, with twisting of the great vessels (*dextroposition* or *dextrorotation*) of the heart. *Situs inversus*, or reversal of all the viscera, may accompany any form of dextrocardia, or it may occur with normal heart position. Neither dextrocardia nor *situs inversus* is of any functional significance in itself, but additional cardiac malfor-

mations are common and may be severe. Mirror-image dextrocardia produces an almost pathognomonic electrocardiogram in the limb leads, i.e., inversion of all waves in lead I and reversal of leads II and III.

Ebstein's Anomaly. The rare anomaly of the tricuspid valve which bears this eponym consists of a congenital downward displacement of the valve into the right ventricle, with anomalous insertion of one or more valve leaflets. The malformation sometimes produces surprisingly little functional disturbance, while in other cases incompetence of the tricuspid valve and impaired function of the right ventricle produce prominent signs at an early age. Sudden death has often been reported.

Although patients with Ebstein's disease are not cyanotic in infancy, they may eventually develop right-to-left shunts through a patent foramen ovale. The right atrium and right ventricle are then greatly enlarged, and the pulmonary vascularity may be decreased. The electrocardiogram shows tall P waves but no signs of ventricular hypertrophy. Complete right bundle branch block and paroxysmal tachycardia are common. There is often a tricuspid apical systolic murmur, which is attributed to incompetence of the dislocated tricuspid valve.

Anomalies of the Aortic Arch. The multiple bilateral aortic arches of the embryo provide a background for a great variety of anomalies. One of the commonest is a *right aortic arch*, in which the ascending aorta arches toward the right instead of the left. The aorta may then continue to lie on the right in its descent, or may cross over to descend in the normal position just left of the midline. In either case, the anomaly is of no functional significance. A right aortic arch may be recognized by its indentation of the barium-filled esophagus, since it impinges on the right side of the esophagus in the anteroposterior view, and displaces the esophagus backward in the left anterior oblique view.

In some cases, both right and left aortic arches persist, forming a vascular ring. Such a ring, which may also result from anomalies of the subclavian or other arteries or from the ductus or ligamentum arteriosum, usually has no effect on cardiac function, but it may produce symptoms by compression of the esophagus or trachea.

Anomalies of the Great Veins. Many variations in the structure of the superior and inferior venae cavae and their major branches are possible. A persistent left superior vena cava, for example, is a fairly common anomaly. Anomalous venae cavae may drain normally into the right atrium and be of no functional significance, or they may drain into the left atrium, producing major venous-arterial shunts. The course of such anomalies can usually be clearly outlined by angiocardiology.

culature (idiopathic hypertrophic subaortic stenosis) is at fault. Both conditions may be associated with similar signs, although it has been stated that the murmur of the latter disorder is more apt to be maximal to the left of the sternum and is less well transmitted to the neck. The angiocardigraphic findings may be of differential value.

The acquired type of subaortic stenosis is usually seen in older persons with left ventricular hypertrophy due to any cause. It is ascribed to unusually vigorous contraction of the muscles encircling the outflow tract. In most instances the pressure gradient between aorta and left ventricle is small and the functional stenosis is of no clinical significance other than the possible confusion with true stenosis. The murmur is the only physical sign in these persons with "pseudoaortic stenosis." Occasionally, however, there may be a thrill with the peripheral signs of true obstruction. In such instances cardiac catheterization will reveal a significant systolic pressure gradient, but the "pull-back" technique (see above) will demonstrate that it is below the valve and hence that surgical intervention is not indicated.

The symptoms and management (except surgical) of subaortic stenosis are the same as those of the valvular variety.

Prognosis. The appearance of syncope on exertion or congestive failure is ominous and that of angina only slightly less so. Nevertheless, there are individuals who may present the characteristic murmur and thrill of aortic stenosis and who survive without symptoms until their seventies or eighties. This must be due to the fact that there is no necessary parallelism between the signs and the degree of obstruction.

Treatment. This consists of the usual precautionary measures against the development of subacute bacterial endocarditis and of the usual management of congestive failure or angina, should they occur. Surgical dilatation of the valve is still hazardous, although an operative mortality as low as 5 per cent has been reported in some series. The decision is difficult because the risk is altogether too great for the asymptomatic patient, and it is still greater when disability has appeared. Yet, when symptoms are present, especially early congestive failure, the over-all outlook statistically is better with surgical than with medical treatment. In facing this problem the physician may wish to recall the statement of Claudius, the stepfather of Hamlet, that,

" . . . diseases desperate grown,

By desperate appliance are relieved,
Or not at all."

We do not believe that any patient should undergo so hazardous an operation unless preliminary left ventricular catheterization reveals a cross sectional orifice of 0.8 cm² or less, as calculated from

the pressure gradient and the blood flow. Likewise, the "pull-back" procedure (see above) should be used to learn whether the valve rather than the subvalvular outflow tract is the site of the obstruction.

AORTIC INSUFFICIENCY

Occasionally, this defect may result from congenital weakness of the root of the aorta, sometimes associated with arachnodactyly or with medial necrosis. It may likewise be produced by a congenital bicuspid valve, usually in conjunction with coarctation of the aorta. In practically all other instances up to the age of thirty, the lesion is due to rheumatic fever. In the thirties and forties, the problem is usually one of differentiation of rheumatic from syphilitic aortic regurgitation, and in the late fifties and beyond from atherosclerotic disease of the aortic valves. In male patients aortic insufficiency may occur as an apparent complication of rheumatoid arthritis or rheumatoid spondylitis. Rarer causes of the valvular defect are bacterial endocarditis, the anatomic disruption of the valve being one of the chief causes of mortality in this condition even when the infection is eradicated; injury to the cusps by trauma; distortion of the valve by dissecting aneurysm; stretching of the aortic ring in severe hypertension, producing a relative regurgitation; and fenestration of the aortic cusps.

When the lesion is advanced, dilatation carries the usual disadvantage of diminished pressure for a given degree of systolic fiber tension (p. 1406) but is advantageous in that it permits filling from the low-pressure atrium despite pronounced regurgitation from the aorta. However, when the volume of this backflow is very great, the left ventricular pressure during late diastole may exceed that in the atrium and so produce diastolic closure of the mitral valve.

Symptoms and Natural History. The patient with aortic insufficiency usually remains asymptomatic for a long period. Once dyspnea on mild effort appears, seizures of paroxysmal nocturnal dyspnea are common, and from this point on congestive failure tends to progress rapidly.

Syncope and angina may occur but are much less frequent than in patients with aortic stenosis. The reduction in coronary flow during diastole because of the lowered aortic pressure is compensated for in part by increased subepicardial flow during systole (p. 33).

Diagnosis. The first problem involves the detection of the lesion; the second is concerned with the recognition of its cause. The high-pitched blowing diastolic murmur heard best at the aortic area or along the left sternal border is the cardinal sign. Sometimes it can be elicited only at the end of held

deformity, evidence of which is essential for the diagnosis of chronic rheumatic heart disease. Nevertheless, all acquired valvular distortions are not of rheumatic origin, and in the following pages lesions due to the other causes are also considered.

Bacterial infection may be superimposed on any valvular lesion. It is relatively uncommon when the valve is extremely deformed or calcified and especially likely to develop upon a valve which has a slight impairment due to rheumatic fever. The simultaneous presence of murmur and fever should arouse the suspicion of bacterial endocarditis and also of an acute flare-up of the rheumatic process.

The precise identification of valvular disease has assumed increasing importance as cardiac surgery has advanced. Such evaluation depends in large measure on the proper interpretation of heart murmurs. The general principles involved have been discussed in Chap. 251. Here, we are concerned with the more practical aspects of valvular disease.

AORTIC STENOSIS

During the first two decades, this lesion is usually due to congenital abnormality of the cusps or of the outflow tract of the left ventricle. Between the ages of thirty and fifty the usual cause is rheumatic fever. In elderly persons, degenerative distortion of the valves is the major factor, although there is some evidence that minimal and clinically undetectable injury by rheumatic fever is often present and predisposes to these changes. At all ages there is a striking predominance of males.

Mechanism of Symptoms. The obstructive lesion at the aortic orifice is rarely of hemodynamic significance until the stenosis has reduced the cross-sectional area by 75 per cent. Eventually, this leads to left ventricular hypertension, with a large pressure gradient across the aortic valve. However, since the flow varies with the fourth power of the radius and only with the first power of the pressure difference, this is not an ideal compensatory mechanism. Thus there occurs an increasingly fixed cardiac output, that is, a progressive inability of the heart to elevate output in response to the metabolic needs of the body.

Syncope on exertion occurs in 10 to 20 per cent of the patients, probably due to the failure of cardiac output to increase as peripheral resistance diminishes in response to muscular exertion. This presumably leads to a sudden fall in cerebral blood flow and hence to loss of consciousness. This symptom has grave prognostic significance, and death usually occurs within 3 years.

Angina pectoris develops in about one-third of the patients. Sometimes it may be caused by the not infrequent coexistence of coronary disease, but it may occur in the absence of coronary obstruction,

and is attributable then to the incapacity of the coronaries to supply a flow of blood to the myocardium adequate to meet the demands of the hypertrophied left ventricle. Indeed, myocardial infarction may ensue even when the coronaries are relatively normal. *Sudden death* occurs in 20 to 25 per cent of cases, as it may in any ischemic heart.

Eventually, if the patient survives, congestive failure appears, becomes increasingly refractory to treatment, and death usually ensues within 2 or 3 years. A curious phenomenon, as yet unexplained, is the persistence of a normal or slightly elevated resting cardiac output even when the left ventricular end-diastolic pressure is elevated (left ventricular failure).

Signs. The classic signs of this disorder are the loud, rough systolic murmur, usually heard best in the second right interspace and transmitted into the neck; the corresponding thrill; the diminished or absent second aortic sound; the slowly rising pulse of low volume (plateau pulse); and the presence of calcification in the region of the aortic cusps as revealed by fluoroscopy. *However, departures from this idealized picture are frequent, and unsuspected aortic stenosis is frequently discovered only at the autopsy table.* The murmur may be loudest at the apex and may disappear completely during congestive failure, reappearing when compensation has been restored. The thrill may not be present, the second sound over the aortic area may be well heard, and the character of the pulse may not conform to the classic description. Finally, calcification of the valves is present in only half the patients, and even then its detection depends on the skill and experience of the fluoroscopist.

Left ventricular hypertrophy is indicated by the forceful thrust at the apex, even though definite cardiac enlargement is usually absent by x-ray. The electrocardiogram may display the characteristic signs of left ventricular hypertrophy, and when coved T waves are present and the R wave is absent in the first three precordial leads, differentiation from an old septal infarct may be difficult or impossible.

Diagnosis. The several varieties of *subaortic stenosis* may present physical signs which are identical with those of valvular obstruction, although the diminution of the aortic second sound is likely to be less pronounced. The distinction is likely to require catheterization of the left side of the heart, with careful "pull-back" observations and the demonstration that the site of the systolic pressure gradient is below rather than at the valve.

Two different types of congenital subaortic stenosis have been described. Surgical treatment may be highly successful when the hindrance is due to endocardial fibrous thickening of the outflow tract, but has little to offer when hypertrophy of the mus-

contraction, while the marked reduction in cardiac output and hence in flow through the very narrow mitral orifice reduces the intensity of the early filling murmur and, very rarely, may even cause it to disappear. However, the other characteristic signs are likely to be marked, and their presence should lead to a meticulous search for the filling rumble under the conditions already mentioned. As a general rule it is not the intensity but *the duration of the murmur which is the most reliable guide to the degree of stenosis.*

Pathophysiology. In the early phase, dyspnea on exertion due to the mechanical effect of the obstruction is the outstanding symptom. The capacity to increase the flow through the narrowed valve is limited, and the increase in venous return with exercise tends to aggravate pulmonary congestion. As the lesion becomes more advanced, two types of compensatory adjustment occur; the clinical picture depends in large measure upon which predominates.

Rise in pressure in the left atrium and in the pulmonary veins and capillaries tends to maintain cardiac output. However, the flow varies with the fourth power of the radius of the orifice and only with the first power of the pressure gradient on the two sides of the valve. Thus, in the presence of significant stenosis, a normal flow can be obtained only by means of a well-marked rise in atrial pressure, which leads to congestion of the lungs. Thus dyspnea is progressive and pulmonary edema, occasionally fatal, may occur when venous return is increased by exertion or fever or when rapid atrial fibrillation causes further impairment of ventricular filling by reducing the duration of diastole. Recurrent hemoptysis due to the development of anastomotic channels between the pulmonary and bronchial veins is common, but right-sided failure may be absent or minimal.

The second method of adjustment is by increase in pulmonary arteriolar resistance. This may be caused by structural thickening of the vessels, by anoxia resulting from pulmonary edema, and perhaps also by reflex vasoconstriction consequent to congestion of the lungs, although the latter mechanism is disputed. When this increase in pulmonary arteriolar resistance is predominant, right-sided heart failure occurs at a relatively early stage, with decline in output of the right ventricle. Thus the pulmonary capillaries are protected against excessive congestion and dyspnea may be relatively slight, despite the presence of the classic manifestations of right ventricular failure. Because of the decline in cardiac output and in flow from left atrium to left ventricle, the diastolic rumble may be faint or even absent, and the opening snap may not be heard. It is this type of patient which may be mistakenly thought to have primary pulmonary

hypertension or myocarditis as the cause of the heart failure.

Both types of compensation are present in most instances, but the extent to which one or the other is predominant tends to determine the outstanding clinical features.

Natural History. Patients with mitral stenosis may survive for many years after the onset of heart failure. In this respect, the disorder resembles tricuspid stenosis but is entirely different from aortic lesions. The latter do not induce symptoms until failure of the left ventricle has occurred, but in the case of mitral stenosis the symptoms are due to the mechanical effect of the valvular narrowing. This may be nonprogressive over a period of many years.

Atrial fibrillation eventually occurs in the great majority of patients and increases markedly the hazard of peripheral or pulmonary embolism. In the absence of such complications, the arrhythmia is compatible with many years of life, provided the ventricular rate is controlled by digitalis. Even so, repeated, massive, and fatal pulmonary infarction may supervene, once right-heart failure has developed.

The frequency of hemoptysis due to collateral venous channels has been mentioned. This manifestation is likewise often the result of pulmonary infarction.

The long-standing congestion due to mitral stenosis leads to important secondary changes in the lungs. Some patients develop extensive hemosiderosis and a pulmonary state not unlike that resulting from one of the primary pneumoconioses. Much more frequently, there is chronic bronchitis with winter aggravation, the symptoms becoming severe with each minor respiratory infection. The prevention and management of such infections are among the important principles of treatment.

When pulmonary hypertension is present, severe pain may occur. This resembles that of angina in its relation to effort but is often of longer duration and responds poorly to nitroglycerin. It is probably due to reduction in the coronary flow relative to the needs of the hypertrophied right ventricle (p. 34).

The thromboembolic complications have been mentioned. The valvular obstruction predisposes to thrombosis in the left atrium, and systemic embolism may occur even in patients with normal rhythm. However, this complication is far more common in patients with long-standing atrial fibrillation. Pulmonary embolism and infarction are rare in the absence of right-sided failure but in its presence are very common. More than one-half the fatal instances display evidence of recent or old infarcts in the lungs.

Bacterial endocarditis is a rare complication of

expiration when the patient leans forward. Most of the patients also have systolic murmurs at the base, and many have them at the apex. The Austin Flint murmur, mimicking mitral stenosis, is frequently heard. The peripheral signs are also important: the wide pulse pressure, the water-hammer pulse, the collapsing pulse, the pistol-shot sound, the double Duroziez murmur, and the capillary pulse—all indicative of a leak from the arterial system and of a peripheral vasodilatation. The x-ray reveals the enlargement of the left ventricle, and when the lesion is pronounced the electrocardiogram displays evidence of left ventricular hypertrophy and "strain." A more reliable manifestation of moderate left ventricular hypertrophy is the exaggerated localized apical thrust.

Two conditions may be readily confused with aortic insufficiency. One of them, fortunately rare, is rupture of a sinus of Valsalva, and the other is patent ductus arteriosus. However, careful auscultation will usually enable one to distinguish between the continuous murmur of these conditions and the to-and-fro basal murmur which is commonly heard in patients with aortic regurgitation. The differentiation from pulmonic insufficiency is considered later.

The recognition of aortic insufficiency due to congenital anomalies, hypertension, or senile degeneration of the cusps will depend in large measure on the age of the patient and the associated findings. The common problem is the distinction between rheumatic fever and syphilis as the cause. Although this differentiation is impossible in some instances, certain points are likely to be of value.

Syphilitic aortic insufficiency should be suspected when a middle-aged individual, usually a male lacking a story of rheumatic fever, presents the classic manifestations of aortic regurgitation. The suspicion is strengthened when there is a history of a primary lesion or of antisyphilitic treatment in the past and when the serologic tests for syphilis are positive (they are positive in about 85 per cent of such cases). The tambour quality of the second heart sound at the aortic area is often present but is also heard in patients with aortic atheroma or hypertension. Hence it is significant only when heard in a comparatively young patient with a normal blood pressure.

Although syphilis does not produce deformity of the mitral valve, the dilatation of the mitral ring consequent to aortic regurgitation frequently causes an apical systolic murmur. Furthermore, the Austin Flint murmur ("relative mitral stenosis") is frequently heard in patients with syphilitic aortic regurgitation, and this murmur cannot be differentiated with certainty from the similar murmur of mitral stenosis. Rough basal systolic murmurs are commonly present, and rarely, a systolic thrill is

felt, but other evidence of aortic stenosis is not encountered. Hence, in an individual presenting aortic insufficiency, the differentiation between syphilitic disease involving the aortic valve only and rheumatic disease involving either the aortic valve only, or both the aortic and mitral valves, cannot be made by auscultation alone. The presence of chronic atrial fibrillation constitutes almost conclusive evidence that the lesion is rheumatic, as does the presence of peripheral signs of aortic stenosis or x-ray evidence of compression of the esophagus by an enlarged left atrium. In the absence of such differential points, the distinction between syphilitic and rheumatic disease has to be made on the basis of the history, the serologic reactions, etc.

Treatment. The management is essentially that of congestive heart failure plus the usual prophylaxis against rheumatic recurrence and against bacterial endocarditis. When syphilis is the cause, antiluetic therapy is indicated but is probably of little value once congestive failure has appeared. Surgical treatment is still experimental and is far less likely to be successful than for aortic stenosis.

MITRAL STENOSIS

This lesion is practically always the result of rheumatic fever. Thus the diagnosis of mitral stenosis automatically implies that the patient has rheumatic heart disease, even though a history of previous joint pains and fever can be elicited in only about 60 per cent of the patients.

In the typical patient, the physical signs are characteristic: the sustained right parasternal heave of right ventricular hypertrophy; the loud staccato high-pitched "snapping" first sound, the exaggerated second pulmonic sound, the short opening click, and the long diastolic rumble with presystolic intensification. The electrocardiogram displays right axis deviation, which is confirmed by fluoroscopic examination, which also indicates prominence of the left atrium with encroachment on the barium-filled esophagus.

In the early stages of the disease, the characteristic phenomenon, the diastolic rumble, may be difficult to elicit. It may be heard only after exercise when the stethoscope is placed at the exact point of the apex thrust, while the patient lies on the left side. The murmur may be very brief and audible only during the brief interval between atrial contraction and the first sound or only during the early part of diastolic filling. At this stage, all the other signs may be absent.

Difficulty may also be encountered when the lesion is advanced. Here, the advent of atrial fibrillation, which is such a common complication, causes disappearance of the rumble associated with atrial

of the problems involved may be more appropriately considered in the subsequent discussion of combined stenosis and insufficiency.

In most instances, this lesion is associated with a faint apical first sound which may be replaced entirely by the loud blowing pansystolic murmur extending into the axilla and even to the back. No opening snap is heard. The apex beat is often of the strong localized type indicative of left ventricular hypertrophy. X-ray examination reveals enlargement of the left ventricle and of the left atrium, and the latter chamber may exhibit systolic expansion. A huge left atrium always signifies the presence of a significant degree of regurgitation. The electrocardiogram usually exhibits evidence of left ventricular hypertrophy, but this may be overshadowed by the coexisting right ventricular enlargement when, as occasionally occurs, there is a secondary marked rise in pulmonary resistance.

The distinction between mitral insufficiency and aortic stenosis, which sometimes produces a murmur loudest at the apex, may present difficulty. The demonstration by phonocardiograms that the murmur begins before ejection is conclusive evidence against aortic stenosis. The leftward transmission of the murmur will usually differentiate mitral insufficiency from interventricular septal defect, which also produces a pansystolic murmur. However, in doubtful instances this separation may require cardiac catheterization.

The recognition of mitral regurgitation due to a dilated ring (relative insufficiency) is easy when there is pronounced cardiac enlargement due to some cause other than rheumatic fever. However, in a patient with obvious rheumatic aortic insufficiency and a markedly dilated left ventricle, the distinction between the organic and relative types of mitral insufficiency may be impossible. The late systolic murmur, which is so frequent in patients with coronary disease, is probably due to mitral regurgitation resulting from distortion of ischemic papillary muscles. It will rarely be confused with the blow of rheumatic mitral insufficiency because the latter is in most instances pansystolic, obscuring the first sound and continuing until very shortly after the second.

Patients with slight incompetence of the mitral valve usually remain free of symptoms but are particularly susceptible to the development of bacterial endocarditis. As the lesion becomes more severe, dyspnea is increasingly pronounced, and once congestive failure begins, it is likely to progress rather rapidly.

The management of mitral insufficiency consists of prophylaxis against recurrences of rheumatic fever (p. 918) and of bacterial endocarditis (p. 1043) and the treatment of these disorders or of congestive heart failure when either occurs. The advent

of open-heart surgery, with the bypassing pump, has made practical the attempts at plastic repair of insufficient mitral valves. However, the hazard is still high and the results are rarely gratifying.

COMBINED MITRAL STENOSIS AND INSUFFICIENCY

A large percentage of patients with rheumatic disease of the mitral valve have a combination of narrowing and regurgitation. However, marked insufficiency requires a large left ventricular output, including both the backward and forward flow, while a high degree of stenosis makes this impossible because it reduces filling. Thus one lesion or the other is predominant. The accurate evaluation of the relative significance of each is a matter of great practical importance in relation to the question of surgical treatment. Such evaluation may be very difficult by ordinary methods and may require catheterization of the left atrium and ventricle, with measurements of pressure and flow and calculation of orifice size. Observation of the effect on pulmonary capillary (wedge) pressure of drugs which alter systemic peripheral resistance may be helpful. Thus norepinephrine may increase the degree of regurgitation, the wedge pressure, and the intensity of the regurgitant murmur, while nitrites tend to have the opposite effects.

Clinical findings, although not always decisive, are often of value in estimating the relative degrees of stenosis and insufficiency.

Systolic Murmurs in Patients with Mitral Stenosis. Aside from mitral insufficiency, there are three other common causes. (1) *Concomitant aortic stenosis.* When this lesion coexists, the additional signs are similar to those of aortic stenosis alone except that the diminished flow into the left ventricle may reduce the intensity of the ejection murmur. The demonstration by phonocardiographic means, that the systolic murmur does not start until ejection, will usually separate it from that due to mitral insufficiency. (2) *Ejection murmurs into a dilated pulmonary artery* occur in most patients with mitral stenosis and may occasionally be as loud as grade IV. The absence of left ventricular hypertrophy and the observation that the intensity is greatest in the left upper interspaces will usually distinguish this murmur from others. Occasionally, the separation from aortic stenosis may require left-sided catheterization, with measurement of flow and pressure gradient and calculation of the size of the aortic orifice. (3) *The murmur of tricuspid insufficiency*, whether due to structural distortion of the valves or dilatation of the ring, resembles that of mitral insufficiency in being pansystolic. However, it is likely to be loudest in the lower left parasternal region and tends to be transmitted to

mitral stenosis. It is more likely to affect the less severely damaged valves.

Diagnosis. The most characteristic phenomenon of mitral stenosis, the diastolic rumble, may be due to other causes. Thus the Austin Flint murmur is often encountered in patients with free aortic regurgitation, even though the mitral valve is normal. This rumble is presumably due to displacement of the aortic cusp of the mitral valve and its vibration between the forward stream of blood from the atrium and the regurgitating blood from the aorta.

When the diastolic flow through the mitral valve is greatly increased, as in patients with patent ductus arteriosus or in those with outspoken mitral insufficiency, a diastolic rumble may occur even though the cusps are normal. In such instances there is relative stenosis, in terms of the size of the valve orifice as compared to the flow through it. Relative tricuspid stenosis with a diastolic rumble may occur when, because of atrial septal defect, right ventricular filling is markedly increased. Structural tricuspid stenosis is almost always of rheumatic origin and associated with mitral stenosis. Atrial myxoma (p. 1465) is a rare cause of a diastolic rumble. Its preoperative distinction from mitral stenosis may be possible only by means of the angiocardigram.

Those several conditions which mimic mitral stenosis by causing a diastolic rumble may be recognized by the signs of the basic disorder and, with the exception of tricuspid stenosis, by the absence of an audible opening snap. Unlike mitral stenosis, they do not cause prolongation of the time elapsing between the onset of excitation and the beginning of the first heart sound (Q-S₁ time).

As has been mentioned, the intensity of the mitral stenotic murmur is related not only to the degree of narrowing but also to the rate of flow through the orifice. Occasionally, when cardiac output is markedly decreased, there may be no audible rumble, despite a high degree of obstruction. The absence of a rumble has also been noted in association with large thrombi in the left atrium. Thus in a patient—usually a young woman—with a rheumatic history, severe heart failure, and no murmur, the slight hazard of left-sided cardiac catheterization, with measurement of the atrioventricular pressure gradient and of cardiac output, is justifiable. Unless this information, which allows a reasonably accurate calculation of the size of the orifice, is obtained one will occasionally overlook a surgically treatable obstruction.

The so-called primary pulmonary hypertension is, like mitral stenosis, usually a disease of young women (p. 1538). The patients may exhibit a presystolic gallop and a split first sound. These auscultatory phenomena may mimic closely the presystolic rumble of mitral stenosis. Both disorders

are commonly associated with clinical and electrocardiographic evidence of right ventricular hypertrophy. However, the shape of the atrial complex is usually different, the P wave being broad and notched in patients with mitral stenosis, and narrow and spiked (P-pulmonale) in those with primary pulmonary hypertension. When doubt exists, there is indication for right-heart catheterization, with measurement of the pulmonary capillary (wedge) pressure, which remains normal in patients with pulmonary hypertension but is elevated in the presence of hemodynamically significant mitral stenosis.

Treatment. Surgical treatment will be discussed later. The medical management consists of prophylaxis against rheumatic recurrences (p. 918), the prevention of thromboembolic episodes, control of atrial fibrillation, and treatment of congestive heart failure (p. 1385). Although these conditions are discussed in detail in other chapters, certain points may be emphasized here.

The presence of a normal resting heart rate in a patient with atrial fibrillation and mitral stenosis does not invariably mean adequate digitalization. It is essential to be certain that slight exertion does not provoke undue tachycardia. Periodic augmentation of a standard maintenance dose of digitalis is usually necessary to ensure optimal digitalization (p. 1387).

The attempt to reestablish sinus rhythm is rarely permanently successful when atrial fibrillation is due to tight mitral stenosis. Following surgical widening of the valve, the likelihood of success is greater. When fibrillation persists, permanent anticoagulant therapy is desirable in order to reduce the hazard of the serious thromboembolic complications.

MITRAL INSUFFICIENCY

This lesion is occasionally of congenital origin, being associated with a low interatrial or high interventricular septal defect. Coronary disease is a not infrequent cause, and in such an instance the murmur is usually in late systole and may appear during anginal attacks and vanish as the pain subsides (p. 1412). Marked dilatation of the left ventricle from any cause may produce relative mitral insufficiency because of dilatation of the mitral ring, the murmur diminishing as improvement occurs. Bacterial endocarditis is a rare primary factor but frequently causes a previously damaged valve to become more incompetent. However, in the absence of marked left ventricular enlargement or of obvious coronary disease, rheumatic fever is by far the most frequent etiologic factor.

The following description of uncomplicated mitral insufficiency will be relatively brief, as many

systolic variety and caused by tricuspid insufficiency, they do not militate against surgical treatment. However, ejection murmurs of aortic stenosis or pansystolic murmurs of mitral insufficiency, while not necessarily constituting contraindications, indicate increased hazard and lesser likelihood of benefit than is the case with mitral stenosis alone.

A diastolic blow associated with the peripheral signs of aortic insufficiency is a contraindication. In the absence of the latter signs, such a blow may signify a slight degree of aortic regurgitation, which reduces the chances of a good result, or the Graham Steell murmur of relative pulmonic insufficiency, which constitutes an additional reason for the operation. If such a blow is audible to the right of the sternum, it probably indicates aortic regurgitation. However, either condition may produce a diastolic murmur, loudest in the left third or fourth interspace at the sternal margin, and in the absence of peripheral signs the distinction between the Graham Steell murmur and minimal aortic regurgitation may be impossible.

Either bacterial endocarditis or an acute rheumatic flare-up precludes operation until these complications have been thoroughly controlled. However, low-grade smoldering rheumatic activity is not necessarily a compelling reason for deferring surgical treatment.

The operation may be done at any age, but the chances of restenosis due to recurrent rheumatic fever are greater in those under the age of thirty. Thus the ideal patient for operation is aged thirty to forty-five, with progressive exertional dyspnea which is beginning to interfere with normal activity, with a prolonged diastolic rumble and no other murmurs, and with clinical, electrocardiographic, or radiologic evidence of right ventricular hypertrophy but little or no increase in the transverse diameter of the heart. If, in addition, there is a history of hemoptysis, of attacks of pulmonary edema, or of systemic embolism in such an individual, operation is almost imperative.

It should be emphasized again that in doubtful instances right-sided catheterization, with measurements of the wedge pressure, may be necessary to distinguish mitral stenosis from pulmonary hypertension consequent to disease of the lungs or to embolism. The same procedure will also identify atrial shunts as the cause of flow rumbles. Catheterization of the left chambers will occasionally be needed to evaluate the relative degrees of stenosis and insufficiency of the mitral valve and to decide whether a coexisting aortic stenosis is of any real mechanical significance.

In patients with evidence of previous systemic or pulmonary embolism, and in persons with longstanding atrial fibrillation, operation should be preceded by several weeks of anticoagulant therapy.

Neither an age beyond fifty-five nor advanced heart failure is a contraindication, provided one is satisfied that mitral stenosis is the sole or chief cause of the symptoms. However, the operative hazard is much greater in patients with severe heart failure. A previous acute pericarditis does not preclude operation, although adhesions resulting from it may add to the technical difficulty. Knowledge from long-term observation that the signs of mitral stenosis are of recent origin is a contraindication because there is a possibility that the rumble is a result of edema of the valves and that the stenotic lesion may disappear with time and with treatment of the rheumatic process.

Surgical treatment may be instituted during pregnancy but, in general, the procedure should be postponed until after delivery.

The operative hazard naturally varies with the stage of the disease. In experienced hands it is less than 1 per cent in those patients (class II) who have no symptoms except exertional dyspnea. It is relatively low even in persons (class III) who have had early congestive failure, with mild symptoms at rest. The formerly high mortality for patients with advanced failure (class IV) is steadily declining.

Opinions differ as to the long-range results. In the experience of the writers, improvement has been striking in many instances, and is sufficient to justify the procedure in most of the others. Failure to improve has usually occurred only in individuals who have presented one or more of the contraindications already discussed, in those who have had mitral insufficiency produced by the procedure, or in those in whom extensive calcification prevented adequate dilatation of the valve. Restenosis, requiring a second operation, has been very rare in patients beyond the age of thirty-five but has occasionally occurred in younger patients.

Types of Chest Pain Following Operation. The multiplicity of painful syndromes which may be observed has been a source of considerable confusion. The following clinical pictures may occur singly or in various combinations.

Nonrecurrent pain in the early postoperative period arising in the pericardium, the pleura, or the wound. This type of discomfort is regularly observed during the first few postoperative days and may endure for several weeks. It is sometimes associated with a pericardial or pleural friction rub and usually appears to be related to a sanguinous or serofibrinous reaction of these membranes to injury. Since a similar disorder of the pleura—but not of the pericardium—may follow noncardiac thoracotomies, it is clear that this syndrome is not related specifically to the heart.

Repeated episodes of fever associated with pericarditis and/or pleuritis (the "postcommisurotomy

the right precordial area rather than toward the left axilla.

These several features, plus evidence as to whether there is right ventricular hypertrophy only, or both right and left, will usually allow these conditions to be separated from mitral insufficiency and from each other. The presence of left ventricular hypertrophy constitutes strong evidence that a systolic murmur is due either to mitral insufficiency or to aortic stenosis and indicates that operative treatment, while not necessarily out of the question, is likely to carry a large hazard. On the other hand, the murmurs of tricuspid insufficiency or of ejection into the dilated pulmonary artery do not militate against mitral valvulotomy.

Diastolic Rumbles in Patients with Mitral Insufficiency. The blowing systolic mitral regurgitant murmur usually extends slightly beyond the second heart sound, because during the early phase of relaxation the pressure in the ventricle is above that in the atrium. Since this early diastolic blow is continuous with the systolic component, it does not cause confusion with the lower-pitched rumble of stenosis. However, there may be a short loud filling rumble when narrowing is minimal or even absent. This is produced by the increased rate of filling consequent to the elevated atrial pressure due to the systolic regurgitation. *Thus a loud filling rumble does not prove a high degree of mitral stenosis.* However, when the valve is not narrowed, early diastolic filling occurs quickly and the duration of the rumble is brief. When stenosis is marked, filling necessarily occurs at a much slower rate and the duration of the rumble is long. Hence a *faint or moderate but prolonged rumble is a more reliable sign of advanced stenosis than is a louder but briefer rumble.*

The methods used to distinguish between right and left ventricular hypertrophy have been previously discussed (p. 1406). Here, it need only be reiterated that the accurate assessment of hypertrophy is of the greatest importance in the evaluation of mitral valvular disease. The presence of any degree of left ventricular enlargement indicates that some additional disorder—usually mitral insufficiency or an aortic lesion—is present, in addition to whatever degree of mitral stenosis the patient may have. In most instances, mechanically significant mitral regurgitation is associated with detectable left ventricular hypertrophy. However, when there is marked secondary rise in pulmonary resistance, this may be masked by predominant right ventricular enlargement.

The inadequacies of the x-ray method of evaluating ventricular hypertrophy have already been mentioned (p. 1406). Some dilatation of the left atrium may occur with either insufficiency or stenosis. However, either extreme enlargement or

marked systolic expansion of this chamber is usually always associated with pronounced regurgitation.

Replacement of the first heart sound by the systolic murmur constitutes strong evidence for a well marked degree of insufficiency; exaggeration of the first sound and the phonocardiographic demonstration of a delay (0.07 sec or more after the beginning of the QRS) of the apical S₁ both speak for stenosis. Normally, the mitral first sound begins very early—0.04 to 0.06 sec after the start of the QRS because of the low left atrial pressure. However, when this function is elevated, more time is required for the left ventricular pressure to exceed that in the left atrium and produce mitral closure.

A loud opening snap points toward mitral stenosis but must be distinguished from the filling gallop which is so common with insufficiency, and which occurs only about 0.04 sec after the opening of the mitral valve. Despite the higher pitch of the opening snap, the differentiation may be impossible by auscultation. Indeed, in some instances, this distinction cannot be made by phonocardiogram alone and requires a simultaneous record of precordial motion in order that one may know when filling actually begins. The recognition of these and of other causes of three-sound rhythms has been considered on p. 1407.

Catheterization of the left side of the heart is attended by a small hazard. However, this is justifiable in doubtful instances. The measurement of the atrioventricular pressure gradient is per se not sufficient to afford an absolute distinction between predominance of stenosis or of regurgitation. However, such measurements, when coupled with determination of cardiac output, allow the calculation, with reasonable accuracy, of the size of the valve orifice. If this is greater than 1 cm², insufficiency is probably the chief lesion, while an orifice of less than 0.6 cm indicates that stenosis is the main disorder. When, as in most patients, the physical signs are conclusive, left-sided catheterization is not essential. However, when doubt exists, this procedure is more useful than catheterization of the right chambers, which even when accompanied by measurement of the wedge ("pulmonary capillary") pressure will not always distinguish clearly between insufficiency and stenosis.

THE SURGICAL TREATMENT OF MITRAL VALVE DISEASE

In the selection of patients for operation, the first problem is that of the detection of valvular disorders other than mitral stenosis. In this respect the evaluation of coexistent systolic murmurs, which has already been discussed, is of great importance. When such murmurs are of the ejection type and due to a dilated pulmonary artery, or of the pan-

this lesion is of congenital origin, except for the unusual instances in which it occurs with malignant carcinoïd, practically always with liver metastases.

Certain other aspects of chronic valvular disease of the heart are considered in the chapter dealing with congenital disorders.

254 ISCHEMIC HEART DISEASE (Angina Pectoris and Myocardial Infarction)

William H. Resnik and
T. R. Harrison

The specific and distinguishing feature of ischemic heart disease is pain due to oxygen deficiency in the myocardium (Chap. 5). The clinical picture depends on whether this deficiency is permanent, complete, and accompanied by necrosis of muscle fibers (myocardial infarction) or temporary, relative, and without concomitant evidence of such destruction (angina pectoris). Both types of myocardial hypoxia are accompanied by a tendency toward sudden death. This is due to ventricular fibrillation, which can be induced in animals by experimental procedures which cause a large oxygen gradient between adjacent normal and ischemic areas.

Congestive heart failure is a frequent but much less specific complication of ischemic heart disease. It may set in abruptly following myocardial infarction, or may appear gradually over a period of months or years. When there is a story of the typical anginal pain, coronary disease is readily identified as the cause of the heart failure. However, when pain is absent, the recognition of ischemic heart disease is likely to be difficult and may be impossible.

The problem of diagnosis in the elderly patient with nonvalvular normotensive heart disease and failure has long been a difficult one. Disregarding those rare instances due to disorders such as amyloid, scleroderma, Fiedler's myocarditis, etc., a high percentage of the remainder will be found at autopsy to have moderate to severe coronary sclerosis. However, this is often no more advanced than that seen in other elderly persons who had been free of clinical evidence of disease and have succumbed to unrelated disorders. Thus in the absence of clear evidence of a critical diminution of coronary flow, either by the presence of infarctional scars or through a previous clinical history of angina or infarction, the relationship between the coronary disease and the heart failure must be uncertain. The application of the term "arteriosclerotic heart disease" to such patients is unjustifiable. It is preferable to speak of "heart disease and failure of undetermined origin." Senile heart disease (Dock's presbycardia, p. 1378) alone, as the cause of heart failure, must be quite rare. Nevertheless, we do not believe that the concept of the aging myocardium as a frequent contributory cause of failure can be in doubt.

It is because of these considerations that we believe the term "arteriosclerotic heart disease" is misleading and should be discarded. "Coronary disease" is preferable but, by definition, includes the large number of insignificant atheromas found at autopsy. However, the term "ischemic heart disease," which is already widely used in Britain, is free from those objections because it implies a disturbance of function and that is what the physician can diagnose and treat.

Disease of the coronary arteries is the single most important cause of death in the United States. In men, atheroma begins in youth and occasionally produces its characteristic clinical effects in the third or fourth decades. More commonly, the process remains asymptomatic until after the age of forty in men, and until after fifty-five in women, who lose their remarkable immunity after the menopause.

The symptoms of coronary atheroma are due not to the intimal roughening but to the ischemia caused by the commonly associated narrowing. When the lumen is not compromised, the process

syndrome"). These attacks may recur for 6 to 18 months or, rarely, over a period of several years. An identical syndrome may follow myocardial infarction (p. 1454) or cardiac trauma, whether of the penetrating or nonpenetrating type. Therefore, the term *postcardiac injury syndrome* is perhaps the most suitable designation. This disorder, of which pericarditis is usually the outstanding manifestation, is considered in more detail in Chap. 256.

Coincidental reactivation of rheumatic fever. This is rare, and there is no proof that it is a result of the operative procedure. When it does occur, the rheumatic pericarditis, pleuritis, or possible myositis may produce a clinical picture which, except for the elevated antistreptolysin titer, is indistinguishable from the postcardiac injury syndrome. The differentiation is of prognostic import because of the greater likelihood of restenosis following rheumatic recrudescence.

Chest wall pain following injury to intercostal nerves. The anatomic relationship of these nerves to the ribs renders them especially susceptible to injury by retractors during the operation. A causalgic syndrome may result and produce troublesome pain (without fever, pleuritis, or pericarditis), which may endure for months. The occasional coexistence of this disorder with the postcardiac injury syndrome is one of the factors which has delayed the clarification of these several painful conditions.

RIGHT-SIDED VALVULAR LESIONS

Tricuspid Stenosis. This lesion occurs in 3 or 4 per cent of all instances of mitral stenosis. The diagnosis should be suspected when intractable but *nonprogressive right-sided heart failure is present* for years, with little or no dyspnea or orthopnea, and when the physical signs of pulmonary hypertension (precordial systolic lift, accentuated second pulmonic sound, and electrocardiographic evidence of right ventricular hypertrophy) are slight. Ascites is sometimes a prominent feature, as is also some degree of icterus due to persistent congestion and fibrosis of the liver. A diastolic or presystolic murmur, increased by inspiration (p. 1410), may be heard in the tricuspid area. X-ray reveals conspicuous dilatation of the right atrium, without enlargement of the pulmonary artery, and the lung fields are characteristically clear.

This clinical picture represents the result of a malady whose pieponderant effect is an obstruction of the tricuspid orifice. However, tricuspid stenosis occurs almost invariably in conjunction with other valvular lesions, notably mitral stenosis, and the clinical phenomena of "pure" tricuspid stenosis are necessarily modified by the hemodynamic conse-

quence of these other valvular lesions. Thus pulmonary congestion, with dyspnea on exertion, may be a prominent feature even though tricuspid stenosis is present. In practice, diagnosis of the latter lesion is difficult and frequently missed. The only certain method of establishing it is by cardiac catheterization and demonstrating a distinct diastolic pressure gradient between right atrium and ventricle. When such a finding exists in a patient with mitral stenosis, both valves may be widened at the same operation.

Tricuspid Insufficiency. This lesion may be due to congenital displacement of the tricuspid valve (Ebstein's disease, p. 1432). Organic tricuspid insufficiency may also be present when associated with a tricuspid stenosis of rheumatic origin. However, the usual cause for this valvular defect is functional: stretching of the tricuspid ring and imperfect closure of the leaflets due to right ventricular failure, commonly secondary to left-sided failure. When tricuspid stenosis can be diagnosed with assurance, a coexistent organic insufficiency of the valve may be suspected when there is pronounced systolic pulsation of the neck veins and an expansile systolic pulsation of the liver, determined by bimanual palpation.

Malignant carcinoid is a rare cause of deformity of the tricuspid valve.

Pulmonic Insufficiency. Organic disease of the pulmonary valve is practically never of rheumatic origin. However, functional pulmonary insufficiency, with a Graham Steell murmur, is common in patients with mitral stenosis and congenital heart disease, that is, in any condition characterized by a marked elevation of pressure in the pulmonary artery. The Graham Steell murmur is nearly always faint (grade 1 to 2) and is usually heard best in the left second and third interspaces. Differentiation of this murmur from the faint murmur of aortic insufficiency is difficult or impossible unless the peripheral signs of aortic insufficiency are to pronounced as to make the existence of the latter lesion certain. In the presence of aortic incompetence and a condition causing pulmonary hypertension, the coexistence of a Graham Steell murmur is impossible to ascertain and is not of much importance.

Experimental studies on dogs have shown that pulmonary insufficiency per se is well tolerated. However, the pulmonary hypertension responsible for the functional leakage through the valve is a serious disorder and, when associated with left-to-right shunts of congenital origin, adds materially to the operative hazard (p. 1417). On the other hand, pulmonary hypertension secondary to mitral stenosis is not a contraindication to operation.

Pulmonic Stenosis. Pulmonic stenosis due to rheumatic fever is also a rarity. Almost invariably

to two interpretations. It may be that some persons are particularly susceptible to the reflex coronary constriction known to occur with the distention of abdominal viscera. On the other hand, it is possible that in such patients increased cardiac output during digestion, not attended by a decline in peripheral resistance such as occurs during exercise, may impose a load on the heart after eating that is greater than occurs during slow walking.

Some patients experience their initial attacks only on assuming the recumbent position, especially on retiring; only later does the angina of effort appear. In other patients, typical angina appears not during the exertion but immediately after. In some of these individuals postural hypotension is present, and the postexertional fall in mean aortic pressure may be sufficient to reduce coronary flow to the point where myocardial hypoxia and anginal pain at rest appear. This is particularly likely to happen in persons receiving ganglionic blocking drugs for the treatment of hypotension.

The location of the anginal pain may differ from the usual site and offer some difficulty of interpretation. Radiation into the neck and to the angles of the lower jaw is not uncommon, and the pain may be felt only there. In some cases, the pain may be experienced only in the back of the neck at about the level of the lower cervical vertebrae, or in the interscapular space, or in the left shoulder (p. 18).

Finally, many patients do not "perish immediately."

Diagnosis. The cardinal clinical characteristics of angina are the steady unwavering chest pain that appears on exertion and that begins to subside promptly on resting. When such history is obtained and, in addition, there is unquestionable and rapid relief of pain, or increased exercise tolerance, after the sublingual administration of an adequate dose of glyceryl trinitrate (nitroglycerin), the diagnosis may be considered established, regardless of the outcome of all other forms of examination.

Diagnostic difficulties may arise from several sources. The patient may be unable to recall whether his pain was related to exertion; or he may be unable to say whether the "tightness" in his chest represents pain or dyspnea. Because the pain may not be described as constrictive or because it appears in an unusual location, the physician may not consider angina as a possibility and hence may fail to ascertain the influence of exercise.

When the patient suffers from the classic exertional angina and later experiences a similar pain at rest, there is usually no problem in recognizing the nature of the rest pain. It is when angina at rest appears as the initial symptom that the diagnosis may be obscure, for other conditions such as hiatal hernia, gallbladder disease, and esophageal spasm may simulate every feature of angina pec-

toris, aside from the characteristic relationship to exertion and the dramatic response to nitroglycerin. Careful study of these instances of angina at rest will sometimes uncover precipitating factors such as emotional strain, paroxysmal tachycardia, hypoglycemia, paroxysms of hypertension due to pheochromocytoma, or mild congestive failure with edema. Since even strenuous exertion may fail to induce an attack in an occasional patient, and since it may not be possible to secure an electrocardiogram during a bout of pain, the influence of nitroglycerin may constitute the sole evidence on which a somewhat equivocal diagnosis may be made. As is true for all such pains at rest, investigations must be made to exclude actual myocardial infarction, or hiatal hernia, gallbladder disease, etc. (p. 1454). However, the discovery of one of these abdominal disorders does not *ipso facto* prove that it was the cause of the pain.

Rarely, a skeletal pain arising in the chest wall or shoulder may seem at first glance to represent anginal pain, for the increased movements of the thoracic cage or the swinging of the arms during exertion may enhance pain arising from these structures. However, the character of the pain and the presence of tender areas in the chest wall or shoulder should clarify the nature of the pain without much difficulty.

The greatest difficulty arises with those patients who have not only angina but also some less serious cause of pain which is in the same general area and has a similar quality. At least a third of the patients with angina have one or more additional types of chest pain. The innocent cause, which is usually of skeletal origin, is then confused with the serious disease unless the patient is subjected to the most careful study (p. 37).

The physical examination is only occasionally helpful in the diagnosis of angina. The finding of aortic stenosis, or of ectopic tachycardia, or of a late systolic apical murmur (p. 1412) makes it probable but not certain that an accompanying chest pain is of anginal nature. If the patient is seen during an attack, an apical or precordial bulge may be felt in about a fifth of the subjects. However, this may be due to some other cause, such as a previous infarction, and is significant in the diagnosis of angina only if it vanishes as the pain disappears.

The common tendency to place a large emphasis on the resting electrocardiogram leads to serious errors in both directions. Misplaced precordial electrodes may give a mistaken impression that the record has changed (Fig. 254-1). Patients who, having had a myocardial infarction, have made a complete clinical recovery usually exhibit abnormal resting records and often have innocent chest pain arising in the skeletal tissues. This may be confu

cannot be detected. However, a roughened vessel, not previously narrow, may be the site of thrombus formation. Therefore, coronary thrombosis, myocardial infarction, and even sudden death may occasionally occur without previous symptoms. When symptoms do occur, they depend not directly on the degree of narrowing of the main arteries but rather on the balance between the progression of this narrowing and the rate at which collateral channels develop.

Etiologic Considerations. The usual cause of ischemic heart disease is atheromatous narrowing of the coronary arteries. The role of dietary and other factors in producing such changes has been discussed in some detail in Chap. 246.

Much less commonly, the coronary arteries may be compromised at their orifices by luetic aortitis or by dissecting aneurysm or affected by arteritis or embolism. The myocardial oxygen supply may also be impaired by congenital anomalies such as the origin of one main branch from the pulmonary artery or a congenital fistula between a coronary artery and a cardiac vein. However, disease of the aortic valves (p. 33), and especially stenosis, is the commonest cause, other than atheroma, of myocardial ischemia.

Conditions which impose a pressure load on the right ventricle may lead to pain which apparently arises in the wall of this chamber, as the result of its increased need for oxygen and the impairment of the normally great systolic flow to it (p. 34).

Ectopic tachycardia frequently induces anginal pain in older persons and may even do so in young patients who present no detectable evidence of structural disease of the coronary arteries.

Diffuse, nonischemic myocardial disease has occasionally been reported as being associated with anginal pain. Presumably, this is due to involvement of the sensory nerve fibers in the myocardium.

Aside from these several anatomic disorders, there are various other conditions which tend either to reduce coronary flow or to increase myocardial oxygen need. Paroxysmal tachycardia has already been mentioned. Anemia, thyrotoxicosis, and hypertension are rarely if ever primary causes of angina, but frequently aggravate it. In persons with coronary disease the attacks are often induced by emotion, eating, cold, or hypoglycemia. Physical exertion has a twofold effect. It increases cardiac work and hence is the commonest precipitating cause of attacks. However, it also tends to promote the development of collateral circulation through the smaller coronary channels. There is evidence (p. 1448) that minimal exercise which is one-half or less of that required to produce pain may actually improve the myocardial contraction, while effort sufficient to cause pain has the reverse effect. This apparent paradox, which was mentioned by William

Heberden in his initial description of angina pectoris, can be readily explained if one assumes that the milder exercise causes greater increase in coronary flow than in cardiac oxygen need, while in the presence of narrowed vessels the more strenuous effort has the reverse effect.

Many patients have attacks of angina appearing during recumbency and especially during sleep. Occasionally, these are precipitated by reabsorption of edema fluid from the legs as the result of the recumbent position, and in such an instance diuretic drugs may prevent the seizures. More commonly, the cause of the nocturnal attacks cannot be established. Various hemodynamic factors such as increased cardiac output in the horizontal position, higher recumbent blood pressure (in subjects with postural hypotension), carotid sinus effects, and in the left lateral position, the higher level of the orifice of the coronary sinus as compared to the arterial ostia have been proposed, but none has been clearly demonstrated to constitute the responsible mechanism.

ANGINA PECTORIS

Clinical Picture. The majority of patients with angina pectoris have pain that conforms closely to the classic pattern originally described so vividly and precisely by William Heberden in 1788. He pointed out that the subjects of the malady are more commonly men past their fiftieth year; that they are seized while walking, especially if uphill, and soon after eating, with a painful, strangling sensation behind the breastbone; the moment they stand still, the pain begins to subside. He also pointed out that the pain often extends into the left arm. Finally, he was familiar with the remarkable termination of the disorder: "For if no accident intervenes, but the disease go on to its height, the patients all suddenly fall down and perish immediately."

It is important to emphasize that the *anginal pain is steady, and its unwavering quality is more important than the adjective that the patient uses to describe it. It is not influenced by breathing, swallowing, or twisting or turning of the body or arms.*

The deviations from this pattern are frequent enough so that some of the more important ones deserve mention. The patient may insist the pain is "burning," not constrictive. It is not uncommon for anginal pain to be attributed to indigestion because it occurs after eating, but in the majority of such cases, the pain is actually precipitated by exercise which happens to be taken after a meal. In a small group of patients, it occurs after a meal, even though the patient remains completely at rest. Indeed, in some of these individuals, angina of effort may be absent. This unusual behavior is open

alterations, which are identical with those commonly observed during the early phase of myocardial infarction ("current of injury"), have been produced in dogs by the temporary occlusion of a main coronary branch. It is, therefore, probable that when seen in man these reciprocal changes indicate predominance of a single large area of ischemia rather than the effects of multiple smaller patches.

The administration of potassium salts may be of value in the differentiation of T-wave inversions of innocent origin (anxiety, hyperventilation, carbohydrate ingestion, etc.) from somewhat similar inversions due to ischemia. Only in the former group is complete abolition of the inversion in all leads likely to occur.

It is essential to bear in mind that the physical examination and resting electrocardiogram can never establish the diagnosis of angina pectoris. All that they can do is to provide information indicating that a cardiac disorder that could cause myocardial ischemia is present. Except when the post-exertional electrocardiogram is characteristic or when one may secure an electrocardiographic tracing during an attack of spontaneous pain, the diagnosis of angina must rest on the history and the response to drugs. It should be reemphasized that anginal pain is practically always rapidly and completely relieved by nitroglycerin, provided the dose taken is sufficient to produce headache and/or flush. The use of old tablets which have deteriorated because of exposure to light is a common source of error. Direct observation of the response to effort and to nitrites will usually prove to be the most valuable method of diagnosis when the story is confusing.

Prognosis. Prognosis is more uncertain in this disorder than in any other chronic disease. Occasionally, a patient may suffer from angina for a period of time, following which the pain may disappear permanently, even with strenuous activity; presumably, completely compensatory collaterals to the previously ischemic area have developed. In others, the severity of the angina may wax and wane over periods of time, depending on the race between the growth of collaterals and the progression of obstructive lesions. Angina may disappear after an infarction; or, frequently, it becomes worse than it had been before. An important point to remember is that, even in patients with infrequent and mild attacks of angina, sudden death is always a possibility. The other extreme is illustrated by a patient we have personally observed who survived for forty-eight years after the diagnosis was made by William Osler.

There is a long tradition that angina disappears with the onset of congestive failure. This is certainly not always true and, when it occurs, is presumably due to the obligatory restriction of activity

FIG. 254-3. This 32-year-old man had been rejected for insurance because of the inverted T waves in the precordial leads. These had been interpreted as evidence of coronary disease. The history, physical examination, and fluoroscopic study revealed no evidence of cardiac disease. The patient was able to perform vigorous and even violent exercise without any symptoms pointing toward cardiac disease.

Four years previously his sternum had been fractured by impact against the steering wheel in an automobile accident. The electrocardiographic changes illustrated are believed to have resulted from a contusion of the heart and are not considered to have any clinical significance. The record illustrates the fallacy of placing predominant emphasis upon the electrocardiographic rather than on the clinical findings.

and not to any inherent incompatibility between the mechanism of congestive failure and of anginal pain.

Treatment. Aside from relief of discomfort, the therapy is aimed at the promotion of collateral circulation and at prevention of further atheromatous deposit and of the common complications, which are myocardial infarction, congestive heart

- S-T segment depression due to anxiety

FIG. 254-4. This man was rejected by the draft board because of a murmur. Since then he has suffered from a chronic anxiety state. This type of depressed S-T junction with an S-T segment rising to the base line may be seen in some healthy persons following exercise and/or tachycardia. It has no significance as an indication of coronary disease (see Fig. 254-5).

FIG. 254-1. This 65-year-old man had symptoms referable to an irritable colon but no clinical evidence of cardiovascular abnormalities. The electrocardiogram was initially thought to point toward coronary disease. X-ray revealed a low position of the diaphragm and of the heart. When the precordial tracings were repeated in a lower interspace, normal configurations were observed. Rigid adherence to rule-of-thumb techniques in recording precordial tracings, without consideration of the anatomic position of the heart, is often responsible for a false positive diagnosis of cardiac disease.

with anginal pain. Other persons who have healed pericarditis, emotional disturbances, old cardiac contusions, or postprandial hypokalemia may also present the combination of T-wave inversion at rest and insignificant chest pain (Figs 254-2, 254-3, and 254-4). The electrocardiogram, though often normal or borderline, is sometimes invaluable in the diagnosis of angina, provided rigid criteria are utilized in interpreting those changes induced by exercise or occurring during a spontaneous attack.

FIG. 254-2. The patient is a healthy 44-year-old man without evidence of cardiovascular disease. The T waves, which were upright in the fasting state, became inverted in V_3 and isoelectric in lead I, 40 min after the ingestion of 100 Gm glucose. When KCl was administered on the following day, the T waves remained unchanged. The record illustrates the fallacy of diagnosing coronary disease, or any type of organic heart disease, on the basis of T-wave inversion alone.

of pain, provided also that little attention is paid to those alterations found in the resting pain-free state.

We see no purpose in subjecting the patient even to the small risk of an exercise test when the story is already decisive. When, however, the history leaves doubt, as in the case of an initial bout of possible angina at rest, one may resort to an exercise test, provided one is reasonably sure that the pain had not been caused by an infarction. There is no virtue in a standardized test. The amount of exercise required to bring on anginal pain or the characteristic electrocardiographic changes is influenced little, if at all, by age, sex, or size. The history should provide the physician with a reasonably accurate idea of how vigorous and how long the exercise should be. Figure 254-5 illustrates diagrammatically the changes that occur with exertion and those which should be considered indicative of myocardial ischemia.

Anginal pain is often a more sensitive indicator than the electrocardiogram, and when exertion under the observation of the physician does induce characteristic pain and when the amount of tolerated exercise is significantly increased by prior administration of nitroglycerin, the result may be considered conclusive, regardless of the outcome of the serial electrocardiograms. If no pain is caused, but the electrocardiogram is decisive (Fig. 254-5), one can be almost equally certain that the patient does suffer from myocardial ischemia. However, a negative electrocardiographic response does not at all exonerate the patient, for in different studies 20 per cent or more of patients with unquestionable angina pectoris have failed to display the electrocardiographic abnormalities characteristic of coronary insufficiency after exercise.

Spontaneous Electrocardiographic Changes. Unless there has been a previous infarction, the electrocardiogram is usually normal during the pain-free state. A few patients continue to exhibit normal records during the attacks, but more often S-T segment depression occurs in multiple leads and vanishes as the pain subsides. This alteration has been interpreted as due to subendocardial ischemia. However, similar changes have been observed in direct epicardial leads from dogs during hemorrhagic shock and from patients with known ischemic heart disease during thoracotomy. Such tracings, indicating scattered regions of ischemia surrounded by large areas of electrically normal tissue, throw doubt on the concept of the subendocardial origin of S-T segment changes. In any case, it would appear that multiple areas of focal ischemia are responsible for the widespread S-T depression commonly seen during anginal attacks.

An occasional patient exhibits, during the seizures, marked reciprocal S-T changes, with elevation and depression in opposite leads. These temporary

barbiturates will vary from one patient to another. Anxiety about the heart which is often a major cause of emotional stress can be partially alleviated by reassurance, including the true statement that many patients with angina live for decades.

Mild physical fatigue is often the best antidote for emotional stress. Thus fishing, golf, and other recreational activities should be encouraged, provided they do not induce attacks and the patient enjoys them. The spectator sports may be harmful because they provide the undesirable effect of excitement without the benefit of mild physical exertion.

Reduction of Cholesterol. Although the problem of diet remains controversial, we believe that restriction of foods rich in saturated fatty acids is advisable. The foods to be avoided are those rich in butterfat, yolks of egg, fats of meat, hydrogenated vegetable oils, coconut, and cocoa butter. Vegetable oil containing a high percentage of unsaturated fatty acids, such as cottonseed, corn, peanut, or soybean oils, are considered beneficial if they are given in large quantities (40 per cent of total caloric intake). Further details of dietary management and of the use of such drugs as triparanol (MER/29), nicotinic acid, and thyroid derivatives are presented on p. 1364. The unpleasant side effects of nicotinic acid can be reduced either by the use of the aluminum salt, which is expensive, or by gradual increments of dosage up to 1.5 to 3 Gm after each meal. The effects of these several substances are additive, probably because the mechanism of the action of each drug differs, and the most effective results are usually obtained when two or more are employed simultaneously.

It is probable that the hypercholesterolemia, which is common in patients with angina, is secondary to distortions of the metabolism of other fats and especially of the triglycerides. The therapeutic implications of this concept are not yet entirely known.

Drugs. Sublingual nitroglycerin is indicated (1) to treat pain, (2) to prevent it, and (3) in conjunction with subthreshold exercise to promote collateral circulation (see discussion above). It should be taken prophylactically before activities, such as sexual intercourse or a tense business conference, which have been found by experience to induce attacks. When used for pain it should be repeated every 5 min until relief is obtained. If this does not occur after several pills, there is a strong possibility of myocardial infarction. The dose varies from one patient to another but in most is slightly less than that required to produce headache.

Long-acting coronary dilator drugs are rarely of striking benefit in patients with mild angina. Their use in the severer variety is discussed later.

Anticoagulants and monamine oxidase inhibitors

are considered later in the discussion of the management of preinfarctional angina.

Frequent premature beats in patients with angina indicate increased likelihood of ventricular fibrillation. They should usually be treated with quinidine or procaine amide, unless there are contraindications to the use of these drugs (p. 1396).

In patients with angina and overt congestive failure, or with nocturnal attacks that are suspected of being precipitated by reabsorption of edema fluid, digitalis and sodium restriction are employed. *Diuretics must be given with great caution*, because of the possibility of potassium depletion and consequent intoxication by amounts of digitalis ordinarily well tolerated. We are familiar with several instances of sudden death occurring within a brief period after diuretics were first employed in patients with ischemic heart disease. In the opinion of some, salt restriction should be practiced by all patients with angina.

Tobacco should be prohibited when it clearly induces pain, premature beats, or pronounced increase in heart rate or blood pressure. It is possibly harmful in others, and its reduction or withdrawal will depend on the reaction of the individual. There is no evidence that alcohol in strict moderation has either harmful or beneficial effects. Coffee and tea should be allowed also unless they can be shown to cause pain, premature beats, or sleeplessness.

Certain additional therapeutic procedures which may be considered in patients with unusually severe or "intractable" angina are discussed later.

Preinfarctional Angina (Coronary Insufficiency)

The choice of a suitable designation for the intermediate form of coronary pain, one that does not fall into the category of effort angina of brief duration or the prolonged pain with unquestionable manifestations of myocardial necrosis, is difficult. "Coronary insufficiency" and "coronary failure" are not accurate, since any pain due to hypoxia of the myocardium, whether brief or prolonged, is due to insufficiency or failure of the coronary circulation. "Status anginosus" simply implies a prolonged pain but does not indicate whether or not infarction is present. "Prolonged angina without evidence of myocardial necrosis" appears to be the most accurate designation, but it is clumsy. The term *preinfarctional angina* is not free from objections, but since prolonged angina is actually a forerunner of infarction in many instances and since, from a physiologic standpoint, it is but one step away from the stage of myocardial necrosis, it appears to us to be the most suitable for the condition under consideration.

Occasionally, preinfarctional angina develops in a previously asymptomatic subject. Much more commonly, its onset is heralded by a sudden worsen-

FIG. 254-5. A. Slight to moderate postexercise depression of the S-T junction with an upsloping S-T segment is of no significance (see Fig. 254-4).

B. Postexercise downslowing S-T segment. This may be due to digitalis therapy. Otherwise, its appearance after exercise is strong evidence of myocardial ischemia.

C. Marked depression of the entire S-T segment. This change, when occurring after exertion and disappearing within a few minutes, is conclusive evidence of ischemia, but few patients with angina exhibit such a marked alteration.

failure, and sudden death. Another aim is to detect and manage certain commonly associated conditions which are likely to aggravate angina. Of these, obesity, diabetes, hypertension, ectopic rhythms, anemia, and thyrotoxicosis are especially significant.

Physical Activity. The circumstances which in-

duce pain should be avoided. Therefore, walking should be reduced during the first 2 hr after meals, or when there is emotional stress. Outdoor activity should be sharply curtailed during cold weather.

There is now convincing evidence that exercise of a degree considerably less than that required to induce the pain is not only harmless but likely to be positively beneficial (Fig. 254-6). It is probable but unproved that, when undertaken after a coronary dilator drug, the desirable effect of widening collateral channels is enhanced. Although the actual amount of activity prescribed will vary widely from patient to patient, according to the severity of the disorder, the general principle that *exertion which induces pain or dyspnea should be avoided, while that which does not cause these symptoms should be encouraged* is applicable to all.

Emotional Stress. All efforts should be made to curtail anxiety and worry. When, as is often true, this aim cannot be achieved, tranquilizing drugs are indicated. The relative value of meprobamate, rauwolfia—with due consideration of its tendency to cause depression in predisposed persons—and of

FIG. 254-6. A, B, C: Q, C, and N indicate, respectively, times of Q of ECG of carotid upstroke and of carotid incisura. At rest (A) the trace is somewhat abnormal because the downstroke of ejection is delayed. Following mild exercise the record (B) is entirely normal, with a large inward motion (downstroke) during systole. Additional exercise which produced anginal pain caused the record to become grossly abnormal (C). The systolic bulge has now returned in exaggerated form and the atrial motion (upstroke before Q) is pronounced, indicating defective ventricular emptying and increased atrial stretch.

D, E, F: The solid and dotted arrows indicate the carotid upstroke and incisura, respectively. The resting record (D) is borderline, showing a rather small downstroke during ejection. Exercise sufficient to produce pain caused a large outward systolic bulge (arrow B in E). The same exercise caused no such effect when undertaken 1 hr after the application of glyceryl trinitrate ointment (F). The precordial trace at this time is entirely normal (Paper speed 50 mm per sec.)

tients respond better to this regime than to the orally or sublingually administered long-acting dilators such as erythritol tetranitrate or pentaerythritol tetranitrate. In a few the reverse seems to be true, and in some patients the alternation of one of these drugs with the ointment appears desirable.

Once the pain has been controlled, the dosage of the ointment should be slowly reduced over a period of several weeks, in order to decrease the likelihood of the patient's becoming unresponsive to nitroglycerin, which otherwise occasionally occurs.

The value of prolonged or permanent anticoagulation is disputed. There is evidence that heparin, although more expensive, is the drug of choice for this purpose.

The monamine oxidase inhibitors are being widely used in patients with angina. There is no convincing evidence that they have any direct action on the coronary flow. Such beneficial effects, occasionally striking, usually questionable, as are observed are perhaps to be ascribed to a central action, with improvement in general outlook and reduction in emotional stress, or possibly, to an effect on norepinephrine metabolism. Some of these drugs may have serious toxic effects. Pending more complete information, they should be employed with great caution and only in those rare patients who do not respond to other measures.

The remaining measures which are valuable in treating preinfarctional angina are those which have already been discussed in the management of the less severe form of the disease. These include for all patients regulation of activity and of diet, plus reduction of emotional stress. The antiarrhythmic drugs, digitalis, diuretics, and potassium salts are utilized when the aforementioned indications exist. Those additional measures which are of prime importance in the preinfarctional type of angina are (1) anticoagulation, (2) frequent minimal sub-threshold exertion, and (3) long-acting coronary dilator drugs. The last two measures are aimed at the promotion of collateral circulation to the critically ischemic regions of the heart.

"Intractable" Angina

In some patients the relationship between progressive narrowing of main arteries and compensatory widening of smaller channels may remain in a state of precarious balance for months, with episodes of angina during the slightest physical or emotional stress and also during sleep. Under such circumstances various special therapeutic measures have been advocated. Among them are some, such as ligation of the internal mammary artery, which have no sound rational basis and which appear to act only by suggestion. The various other surgical procedures aimed at increasing myocardial blood supply are still to be regarded as being in the experi-

mental stage. Interruption of afferent pathways by direct section or by alcohol injection and reduction of the demands on the heart by the administration of radiiodine are rarely if ever indicated. The so-called intractable angina is actually a chronic form of the preinfarctional type. There is no convincing evidence that any of these procedures prevent the massive infarction or the sudden death which may occur despite the most vigorous therapy. In any case, the large majority of patients survive and improve when the conservative plan of management which has been discussed is applied for several weeks. A goodly percentage of them eventually return to useful but restricted activity.

The surgical treatment of angina due to aortic stenosis is an exception to these general statements. Although the risk remains high, this procedure is entirely justified in properly selected patients (p. 1435).

ACUTE MYOCARDIAL INFARCTION

Coronary occlusion, coronary thrombosis, and myocardial infarction are often used synonymously, although the last term is the proper clinical designation for the condition to be discussed. Myocardial infarction is always the result of a gross discrepancy between the blood supply and needs of the myocardium, usually developing so rapidly that compensatory flow through collateral channels is inadequate to nourish the compromised area of myocardium. This may take place as a result of progressive atherosclerotic narrowing, with or without thrombosis or hemorrhage at the site of a sclerotic plaque, or of any of those circumstances responsible for increased load on the heart or diminished coronary flow described under Preinfarctional Angina (p. 1450), provided they are sufficiently severe and prolonged. Among the rarer causes are coronary embolism, occlusion of a coronary ostium by luetic aortitis, dissecting aneurysm, and polyarteritis. Right ventricular infarction is quite uncommon (about 3 per cent), the immunity of the right ventricle being due to the lesser work load and the proportionately greater coronary reserve.

The Classical Clinical Picture. In the usual case, the patient is seized with a chest pain similar to that of angina, except that it is unrelated to exertion. It is more intense and prolonged, tends to radiate more widely, and is not ordinarily influenced by nitroglycerin. The pain usually is described as having a constrictive quality, it tends to reach a peak rapidly, and it remains at this level without wavering from moment to moment; in other words, it is a *steady* pain, not affected by bodily movements or breathing or swallowing, an extremely important diagnostic feature. Shortly after the onset of the pain, the patient perspires profusely,

ing of previous exertional angina, the attacks appearing with much less effort than before and also occurring frequently at rest.

Prolonged, frequent, and severe anginal attacks appearing at rest or with minimal exertion are likely to be observed under any of three conditions. In a few patients they may be induced by an *increased load on the heart*, such as severe emotional stress or the excessive ingestion of salt. When the cause is removed, the patient will usually return to the previous state, having only brief and milder pain with exertion.

Less frequently, severe and prolonged angina is initiated by some condition such as dehydration, hemorrhage, shock, ectopic tachycardia, or pulmonary embolism, which *reduces cardiac output* and thus causes further decline in blood flow through a coronary system already compromised by atheromatous disease. Of particular importance are those instances in which the circulatory failure induced by an initial myocardial infarction may lead to ischemic pain in other myocardial regions and thus be a threat of more extensive infarction.

More commonly, however, these prolonged and severe attacks are not associated with demonstrable increase in load or decline in output, but apparently with progression of coronary obstruction and an *increasingly unfavorable balance between narrowing of main branches and widening of collateral channels*. The patient now begins to have attacks of increasing severity and duration on less and less exertion and to be awakened frequently by seizures. Some patients may have only one such attack of prolonged pain. The electrocardiographic changes may be absent or minimal, but records during the pain will usually exhibit depression of S-T segments in multiple leads (p. 1446).

The traditional distinction between acute myocardial infarction and preinfarctional angina is a somewhat artificial one since daily measurements of transaminase over a period of 1 or 2 weeks have shown that most instances of the latter disorder are actually associated with some tissue necrosis. The area destroyed is often so small that the other signs of infarction, such as fever, leukocytosis, elevation of the sedimentation rate, overt congestive failure, and permanent electrocardiographic changes, are lacking. Thus one is not justified in an attitude of complacency when the usual signs of infarction are absent, since preinfarctional angina appears to be frequently caused by a partial or even a complete closure of a coronary branch, and the collateral blood supply to the involved area maintains a tenuous balance between supply and need. Without proper therapy, a fairly high percentage of the patients will, within a short time, develop a much more severe attack with unquestionable infarction. Thus, in one large series, about 50 per cent of

those untreated or inadequately treated developed a frank myocardial infarction, while this occurred in only 7 per cent of those properly managed.

Treatment. The patient should be hospitalized. The sedimentation rate, transaminase, and electrocardiogram must be repeated frequently. An accurate pain diary should be kept by the patient and should include meals as well as the exact time of onset and relief of the pain, the number of sublingual pills, and the time and dosage of long-acting coronary dilator drugs. In order to facilitate widening of collaterals, slow brief walks should be taken every hour when awake provided they induce no pain, which they usually do not, and also provided there is no clinical or electrocardiographic evidence of infarction. Unless a contraindication, such as an active peptic ulcer, exists, heparin should be administered for several weeks. When economic or other reasons make this impractical, one of the coumarin drugs may be employed.

There is wide difference of opinion concerning the long-acting coronary dilator drugs. Assessment of their value is made difficult by spontaneous fluctuation in the severity of angina, by the necessity for separation of psychic from pharmacologic effects, and by those subconscious preconceptions which affect all physicians. There is pressing need for the most rigidly controlled "double blind" studies on a very large series of patients. Pending such, one must rely on such sparse objective evidence as is available, plus clinical experience tempered with Osler's optimistic skepticism. Subject to these reservations, our present opinion of these drugs is that despite an occasional exception most of them are of limited value in most patients. However, nitroglycerin ointment (Nitrol) is usually effective as demonstrated not only by (1) the appearance of the typical headache, indicating a pharmacologic effect, and (2) an abrupt decrease in the number of attacks of pain, but also by (3) objective evidence of improved myocardial contraction (Fig. 254-6).

The 2 per cent nitroglycerin ointment should be applied to the skin and spread as thinly as possible without massage. The initial dose should be a 1-in. column as measured from the containing tube, and should be progressively increased until one has determined the largest dose which can be taken without unpleasant side effects (commonly, headache; rarely, postural hypotension). This will usually be 1½ to 2 in. The ointment is applied every 4 hr, an alarm clock being used to prevent omission of the midnight dose. If the diary shows that the pain is appearing at the height of the ointment's action, 1 to 2 hr after application, the dose should be increased. The occurrence of pain as the drug's effect diminishes, 3 to 4 hr after application, calls for greater frequency of administration. Most pa-

for the appearance of unquestionable electrocardiographic and transaminase alterations; the development of the typical picture of shock of obscure origin, again recognized only by these same diagnostic findings; focal cerebral symptoms, such as a hemiplegia, caused either by a sudden drop in blood pressure with impairment of blood flow through a sclerotic but hitherto asymptomatic cerebral vessel, or by an embolus originating in a mural thrombus overlying a painless infarct or scar. It is important to bear in mind that painless infarctions occur not uncommonly during anesthesia or postoperative narcosis or in the course of illnesses, such as diabetic acidosis, which impair consciousness.

Complications. There are a relatively limited number of serious complications that introduce special problems of management and that are responsible for most of the deaths in acute myocardial infarction.

Shock. When, at the onset of the attack, the systolic blood pressure level falls below 80 to 90 mm Hg in a previously normotensive person or below 110 to 120 mm Hg in a previously hypertensive patient and remains at these low levels for 2 hr or more, and when this fall is associated with the clinical picture of shock, the prognosis is extremely grave, over 90 per cent ending in death unless prompt treatment is administered. The cause of the shock is not fully understood; a major factor in most instances must be the sudden decline in cardiac output. This cannot be the whole story, however, for occasionally one sees shock as the initial manifestation when there are no signs of acute left ventricular failure (gallop rhythm, basilar rales) and almost no evidence of myocardial necrosis except a minimal elevation of the serum transaminase. There is some experimental evidence that obscure reflexes arising from the heart play a contributory role.

Acute Pulmonary Edema. In the earliest stages of a severe attack, the sudden impairment of contractile power of the left ventricle may lead to serious or fatal pulmonary edema. This is usually associated with more or less severe shock; signs of systemic congestive failure are absent. If the patient survives for more than a day or two and left ventricular contractile power fails to recover, or if he has improved and a complication supervenes that imposes an additional burden on the heart (ruptured septum, new infarction, ectopic tachycardia), the picture of systemic congestive failure appears.

Abnormal Rhythms. The appearance of an ectopic tachycardia, which can be of any type, may suddenly alter the course from one that is progressing favorably to one of grave danger. The harmful effect of the tachycardias is due to the rapid rate with its accompanying relative increase in systolic

contraction time and abbreviation of diastole. The net result is increased work of the heart, diminished coronary flow and cardiac output. Heart block of either high second degree or complete block introduces the risk of ventricular standstill or fibrillation; fortunately, the block almost invariably disappears within 2 weeks, provided the patient survives.

Rupture of the Myocardium. Rupture of the free wall of the ventricle at the site of the infarction with rapid development of cardiac tamponade occurs in about 10 per cent of the fatal cases; the incidence is higher in older patients beyond seventy and is particularly likely to occur in older women. Rupture is apt to develop within the first 14 days, and death occurs so rapidly that it is rarely possible to determine which of the causes of sudden death has been responsible. Rupture of the interventricular septum is much less common. The diagnosis is suggested by the appearance of a loud systolic murmur at the lower left sternal border, often associated with a systolic thrill, the rapid increase in congestive failure, and death within a week. Rarely, a patient with this complication may live for several years. Far more uncommon than either of the above forms of rupture is the rupture of an infarcted papillary muscle, which is responsible for the sudden appearance of murmurs, loudest at the apex, and the development of a fatal pulmonary edema within a few hours. The appearance of a late systolic murmur unassociated with heart failure is not uncommon and does not signify myocardial rupture. It is probably due to a distortion of a papillary muscle by the ischemic process. If the heart enlarges markedly, the pansystolic murmur of a relative mitral insufficiency may appear.

Thromboembolism. Systemic embolism arising from left ventricular thrombi may lead to serious or fatal complications: gangrene of the legs, hemiplegia, occlusion of abdominal vessels, etc. Much more common are pulmonary emboli, sometimes due to a right ventricular mural thrombus overlying a septal infarct, but far more often due to emboli originating in the deep veins of the legs. Finally, a second myocardial infarct due to development of another coronary thrombosis may occur while the patient is recovering from the first. These various thromboembolic complications are less common at present than before the widespread employment of anticoagulant therapy.

Other Complications and Sequelae. During the past few years, increasing attention has been directed to the post-myocardial-infarction syndrome. This usually occurs within 2 months after the acute infarction, in about 3 to 5 per cent of the cases. Recurrences may develop up to 2 years or even later. The characteristic features are fever, leukocytosis, pleuritis and pericarditis—often with effu-

skin becomes pallid, cool, and moist, and there is a moderate drop in blood pressure. At the same time, dyspnea, weakness, and faintness occur; nausea and vomiting are common. The heart rate is increased somewhat, although occasionally it remains as low as 70 to 80; an early diastolic gallop rhythm is frequently heard, and fine and medium moist rales are audible at the bases of the lungs. After a variable period of time, the manifestations of shock disappear, and the pain gradually subsides, leaving behind a dull ache that may persist for a few hours or up to a day or so. Within a few hours after the beginning of pain, leukocytosis is observed, followed by fever; still later, usually between 24 and 48 hr after the onset, the sedimentation rate becomes elevated. In the more severe cases, the white blood count rises to 12,000 to 20,000 and may remain elevated up to 10 to 14 days; the fever reaches levels of 100 to 103°F, usually subsiding within 10 days; the sedimentation rate may be elevated for 3 or 4 weeks. The serum transaminase usually begins to rise in 6 to 12 hr and reaches a peak within 24 to 48 hr and then subsides to normal levels in 4 to 7 days. In about 80 per cent of the cases, characteristic electrocardiographic alterations are noted: S-T elevation followed by inversion of the T waves and the appearance of Q waves. In the remainder, the electrocardiographic abnormalities, absent in the first day or two, are observed to appear within 7 to 10 days provided daily tracings are recorded. A small percentage of patients exhibit only minor and nonspecific alterations or no abnormalities at all even in the presence of an otherwise classical clinical picture.

After the first day or two, when the pain has usually disappeared, the patient may be so free of subjective symptoms that it may be difficult to persuade him of the seriousness of the attack and of the necessity of several weeks of careful management. The gallop rhythm and the basilar rales may persist for as long as 2 to 3 weeks. Sometime during the first week, usually after the first day and before the seventh, a pericardial friction rub may be heard in about 10 to 15 per cent of cases. The pericarditis is usually asymptomatic but may rarely be associated with mild pain aggravated by breathing.

The above description applies to patients suffering an attack of moderate severity. In milder attacks, all the clinical manifestations are correspondingly reduced, some even being absent, and the evidence of myocardial necrosis (fever, elevated sedimentation rate, and leukocytosis) is minimal or absent. Practically invariably, however, the serum transaminase is slightly increased or displays variations of range greater than 12 to 15 units, even though the highest figure may be less than 40. On the other hand, in the most severe cases, shock is

profound and may last for hours or even days, death being prevented only by the most vigorous therapy. Pulmonary edema and later systemic failure are more pronounced. Cardiac output may be so reduced and peripheral blood flow so impaired that cerebral infarction, gangrene of the extremities or bowel, or acute tubular necrosis of the kidneys may ensue.

The severity of the attack, which is an important guide to the immediate and distant prognosis, is judged not by the extent of the electrocardiographic alterations, but by the total clinical picture and the magnitude of those manifestations which signify myocardial necrosis. The more severe the signs of left ventricular failure (dependent, in addition, on the preexisting condition of the myocardium), the more profound the shock, the higher and longer the duration of the fever, serum transaminase, leukocytosis, and sedimentation rate, the greater has been the myocardial damage, regardless of the appearance of the electrocardiogram. The converse is also true: when all the above phenomena are minimal, the myocardial insult has been small, even in the face of an electrocardiogram that may be interpreted as revealing "massive" infarction (QS waves in all or most of the precordial leads). The electrocardiogram is invaluable in substantiating a clinical impression of acute myocardial infarction; it is of little value in informing us as to the gravity of the attack. Of all the laboratory tests, the transaminase level is the one that parallels best the actual severity of the infarction. Figures of 300 or more always indicate a large and probably fatal infarction. One must bear in mind, however, that a very high transaminase figure that is altogether inconsistent with the mildness of all other clinical signs and symptoms may be caused by central necrosis of the liver lobules, particularly prone to occur if the initial fall in blood pressure is rather severe and prolonged. There is some evidence that estimations of serum lactic dehydrogenase activity may provide more accurate information than does the serum glutamic oxalacetic transaminase activity, now almost universally employed.

Mode of Onset. Myocardial infarction may present itself in a wide variety of pictures aside from the usual and classical one depicted above. A completely painless and symptomless infarct may be discovered in an electrocardiogram taken on a presumably healthy and active person who is simply having a routine checkup. There are a number of other forms of painless infarction, and these may present themselves as acute pulmonary edema or the sudden and rapid worsening of congestive failure; development of arrhythmias, such as heart block, ventricular tachycardia, atrial flutter, or fibrillation; transitory syncope that may not appear to differ from an ordinary innocent faint were it not

that, since by definition, the chest pain has occurred spontaneously, we cannot derive any assistance from provoking or relieving factors; and since the character and location and reference of the pain may be identical in all the disorders enumerated, one can reach a diagnosis only by consideration of corollary features, clinical and laboratory, that may be present at the onset or that may appear after a day or several days of observation. Thus we refer, to name only some of the items, to the development of manifestations of thrombophlebitis especially in a person confined to bed and of the x-ray findings in the chest indicative of pulmonary infarction (acute pulmonary embolism); or the distribution of pain at a distance far more remote than could be attributed to infarction, inequality of arterial pulsations in upper and lower extremities, appearance of a new diastolic murmur typical of aortic insufficiency (dissecting aneurysm); or the development of fever and pericardial friction rub from the very onset of the pain or within 2 to 4 hr, the early aggravation of the pain by breathing, swallowing, or change of position (acute pericarditis); or the information contributed by the serum amylase, bilirubin, alkaline phosphatase or by x-ray studies in the diagnosis of hiatal hernia, gallbladder colic, acute pancreatitis, and perforation of peptic ulcer. Often, even if one does secure unassailable evidence of an acute pericarditis, one still remains in doubt as to whether one is dealing with an acute, benign (viral) pericarditis or the pericarditis of post-myocardial-infarction syndrome.

Finally, in the interests of completeness and accuracy, one must add that there are instances of chest pain (or high epigastric pain) in which the corollary data at the onset or acquired after observation are insufficient to permit one to arrive at a diagnosis with anything approaching certainty and in which one must concede that one can speak only in terms of relative probability or possibility.

The differentiation of the various causes of chest pain is not the only problem introduced by the question of acute myocardial infarction. We have already enumerated the syndromes that may be caused by acute painless infarction: syncope, shock, sudden dyspnea and congestive failure, cerebrovascular episodes. Each one introduces its own problems of diagnosis and, once again, the solution is not always simple and certain. There is no royal road to the diagnosis of acute myocardial infarction, not even when the road is traveled by the most astute and experienced clinician.

Prognosis. The prognosis is always uncertain. The patient apparently progressing most favorably may die suddenly and unexpectedly; another person, desperately ill, may recover to lead a useful active life. Statistics based on a large series of cases may give a general idea of what happens to large

numbers of patients, but they are utterly worthless in assisting one in the prognostication of an individual patient because the outcome depends in each instance on a great many variables: the size of the infarct, the damage inflicted by previous and possibly silent infarcts, the inherent reserve of the myocardium, the presence of serious concurrent disease, the development of unpredictable disasters, such as rupture, serious arrhythmias, recurrent coronary occlusions, and other thromboembolic phenomena. In general, if the patient has surmounted the initial insult to the myocardium and has survived beyond 21 days when rupture and ectopic rhythms are most likely to have occurred, the chief risk is the development of a thromboembolic complication, now minimized by anticoagulant therapy. At no time, however, is the risk of sudden death due to ventricular standstill or fibrillation absent.

Treatment. The first principle is that the treatment should be directed at the patient rather than at the electrocardiogram. This is especially important in the decisions concerning activity and return to work.

During the first few hours, complete rest is indicated, and sufficient opiates or other analgesics should be used to relieve the pain. Food may be restricted to fruit juices for the first 24 to 48 hr, and water given in amounts of 1,000 to 1,500 ml, or more, depending on the extent of the loss by sweating. Enough fluid should be given to ensure a urinary output of at least 700 ml. The intravenous route for administration of fluids and drugs should be avoided except when imperative. If there are numerous rales in the lungs, or if cyanosis is present, oxygen is urgently needed. Even in the absence of these signs, oxygen is probably of value, as the elevation of the arterial oxygen content, although small in degree, will allow a given level of tissue oxygen tension to be achieved at a lower level of cardiac output and may, therefore, rest the heart. It has been demonstrated in animals that the oxygen content of the marginal areas around the infarct is increased by the administration of oxygen.

Despite the risk of anticoagulant therapy, such as the occurrence of bleeding, of increasing the gravity of cerebral and other embolisms, of promoting the development of hemopericardium, the benefits accruing from this form of therapy now appear definitely to outweigh the risks. Inasmuch as a serious thromboembolic episode may occur even in an individual who has sustained only a mild infarction, we believe that it is probably wise to administer anticoagulants to all persons, provided reliable laboratory control is available and the patient is cooperative. Heparin is unquestionably the best anticoagulant, and it may be given in doses of 50 to 75 mg every 6 to 8 hr intravenously, or with a

sion—and pneumonitis; the pleural and pericardial exudates may be hemorrhagic. It is evident that the clinical picture is practically identical with that of the postcommissurotomy syndrome, and it has been postulated that both syndromes have a common basis: sensitization to antigens resulting from myocardial necrosis (p. 1468). The importance of the syndrome lies in the fact that it is generally a benign disorder but that it may be mistaken for a recurrence of myocardial infarction.

Ventricular aneurysm occurs in about 20 per cent of cases within weeks or months after the acute attack. It is more frequent in hypertensive persons, usually appearing at the apex or anterior wall of the left ventricle, and it may be recognized at the bedside by the observation of a large area of pulsation that is distinctly independent of the apical pulsation. By x-ray, abnormal bulges of the ventricular contour and a paradoxical pulsation may be witnessed. The aneurysm practically never ruptures and in most instances does not alter the prognosis.

The shoulder-hand syndrome is characterized by pain and tenderness of the shoulder, followed by pain, redness, swelling, and stiffness of the hand and fingers, occasionally terminating in atrophy of the small muscles of the hand. The cause is unknown. The syndrome occurs in 5 to 10 per cent of patients and develops any time within a year following the attack (p. 1923).

Perforation of or massive hemorrhage from a peptic ulcer may develop during an acute myocardial infarction and is possibly caused by increased adrenocortical activity.

The Problem of Acute Prolonged Chest Pain (Diagnosis of Acute Myocardial Infarction). We are here concerned with the question of acute, prolonged chest pain, steady and unwavering, persisting for 20 min or more, unprovoked and uninfluenced by exertion, breathing, swallowing, turning or twisting of chest or shoulders or by any other bodily function or activity; unrelieved by nitroglycerin, and subsiding spontaneously or only after the administration of a narcotic. One is faced not only with the problem of deciding whether the patient is suffering from infarction or preinfarctional angina (p. 1449) but also with the possibility that any one of a number of other conditions aside from acute myocardial ischemia may have given rise to this type of pain. It is simple enough to lay down rules of differentiation when each of these disorders presents itself in so classical a form that confusion, one with the others, constitutes no serious problem. But there are a number of circumstances that often interfere with the ready solution of the matter.

In acute myocardial infarction, the characteristic electrocardiographic alterations may be absent during the first few days or even throughout the entire

course; or they may be obscured by electrocardiographic changes caused by previous and now completely healed infarcts or by left bundle block or left ventricular hypertrophy. The introduction of the serum transaminase test has been of great value, but quite aside from the elevations associated with necrosis of the liver or with acute pancreatitis, we must bear in mind that chest pain with an accompanying elevation in the transaminase level may be due to an *acute pulmonary embolism*, the transaminase increase being caused by involvement of skeletal muscle adjacent to the thrombophlebitis responsible for the embolus. Moreover, the characteristic electrocardiogram of acute cor pulmonale occurs too infrequently to be of much assistance. The combination of elevated lactic dehydrogenase, normal transaminase, and increased serum bilirubin is suggestive of pulmonary infarction; increase in the serum level of both enzymes with little or no elevation of bilirubin points toward myocardial infarction.

If one lays any stress on the "tearing" pain said to be characteristic of *dissecting aneurysm*, one relies on a myth that has been conjured up by writers who assume that a tear should be associated with a "tearing" pain. The chest pain of dissection aneurysm is identical with the pain of acute myocardial infarction, and if perchance, a rare individual happens to use the term "tearing," the adjective means little or nothing; it is employed just as frequently, or more accurately, rarely, by patients who suffer from other disorders aside from dissection aneurysm. It is often written that a distinction between the pain of dissection aneurysm and myocardial infarction may be made on the basis that the former reaches its peak very rapidly or instantaneously. We have found this point, too, of value only occasionally, since patients suffering from a severe pain of this type are rarely able to give a clear story about the rapidity with which the peak is reached. Finally, the dissection may involve a coronary artery, in which case dissection aneurysm no longer merely mimics but actually causes infarction.

The pain of *acute pericarditis* may for the first few hours have a steady quality indistinguishable from that of acute infarction, and it may be referred to the arms and back or jaws in identically the same manner.

In a very high percentage of cases, pain due to *hiatal hernia*, *gallbladder colic*, *acute pancreatitis*, *ruptured peptic ulcer* is centered at or below the level of the xiphoid, whereas the pain of acute myocardial infarction is centered above these levels; but occasionally, pain may be distributed in an atypical fashion, the former above and the latter below the xiphoid (p. 16).

The lesson to be drawn from these reflections is

involving the pectoral muscles, only reassurance, aspirin, and heat are necessary. In the more severe forms, steroid therapy or a stellate ganglion block may be beneficial.

Post-myocardial-infarction Syndrome. Aside from symptomatic relief, nothing needs to be done unless the fever and tachycardia constitute a threat, in which case cortisone or a derivative usually confers dramatic benefit. Because of the possibility of the development of a large pericardial effusion when anticoagulants are given in the presence of an extensive pericarditis, the patient should be observed very closely for early signs of tamponade. In the latter case, the pericardium should be tapped promptly.

Anxiety States. Emphasis has been directed repeatedly at the importance of psychologic management in all cases of disorders of the heart. In none are sympathetic understanding and insight into the emotional problems of the patient more necessary than when dealing with individuals who have suffered a myocardial infarct. Most of these patients are stricken at the height of their business or professional careers and of their responsibility to family and colleagues. The ominous significance of "heart attack" and "coronary thrombosis" has attained such wide diffusion among the laity, especially through reports of the unexpected deaths of friends who but a few days before had seemed robust and well, that hardly anyone who has sustained such an attack can fail to ponder anxiously on what the future will hold for him. Aside from the immediate threat to his life, the questions of his capacity to carry on his business, job, or profession, and of the far-reaching influence this illness will have on the lives of his wife and children, must obtrude on his thoughts. It is not necessary to discuss the innumerable anxieties that inevitably attend the convalescence of the person who lies in bed or leads the restricted life following the acute attack. Suffice it to say that these ideas do preoccupy a large part of his thoughts, and recognition of their existence must not be overlooked by the physician, however impassive and philosophic the patient may seem to be. It is during these days that the physician must exert his utmost skill in restoring confidence, in explaining in simple terms the significance of the illness, and in allaying fears and anxieties. The task is not easy, for the physician cannot forget that behind the apprehensions of the patient there is a core of truth that can never be dissipated. He can, however, come to a reasonably accurate estimate as to the degree of activity in which the patient may ultimately participate; and he can, within the limitations imposed by a malady of such uncertain course, encourage a life that will often be more active and useful than the patient had imagined. He can point out the many useful and pro-

ductive years that others suffering from the same disorder have experienced. The details and the intricacies of this problem will be as varied as the temperaments and the circumstances surrounding each individual patient. The administration of drugs and the supervision of strictly medical measures constitute a progressively diminishing part of the total management as the days of the acute attack recede and the days of convalescence and resumption of more or less normal life progress.

The question arises as to how soon a patient may resume his work after a myocardial infarction. The answer should never be based on the electrocardiogram alone, but rather on the total clinical picture: the severity of the attack and the rate and completeness of recovery as well as the nature of the patient's occupation. There can be no rigid rules. The individual who has sustained a mild attack may be permitted to return to work within 4 to 6 weeks, whereas the patient who has suffered a more serious attack may require many weeks or months, or may never be able to return to work again, particularly when the occupation is one in which strenuous exertion is unavoidable. The physician should never advise a change of occupation unless such a step is imperative. Searching for a new position, becoming accustomed to unfamiliar duties may impose far more stress on the heart than continuing at the old occupation.

Long-term Management. Long-term anticoagulant therapy should be employed only when the patient is intelligent and cooperative, the laboratory controls are reliable, the physician is familiar with this form of treatment, and there are no contraindications such as have been enumerated above. Even under such optimal conditions there is uncertainty concerning the value of prolonged anticoagulant treatment. Restriction of saturated fats and reduction of weight to the ideal level for the person's height are also of importance. Regular exercise, such as walking or playing golf, is beneficial, provided it does not provoke angina or dyspnea. Moderate use of alcohol, coffee, and tea is permissible, and tobacco should be discouraged, although we have seen few patients who have observed this last admonition.

small amount of procaine subcutaneously. The expense and the inconvenience of so many punctures usually persuade the physician to employ one of the oral drugs, either one of the coumarins or indandiones, after the first 2 to 3 days. Bishydroxycoumarin (Dicumarol), warfarin (Coumadin), and other derivatives and the indandiones are all reliable and effective. It is important that the physician become thoroughly familiar with the behavior of one drug and stick to it; that the prothrombin times be dependable; and that vitamin K₁ (Mephyton) always be immediately available if hemorrhage or dangerous prolongation of prothrombin time should occur; and that this type of therapy be omitted in any patient with a hemorrhagic diathesis, with known ulcerative disease of the gastrointestinal tract or any other localized bleeding lesion, or with seriously disturbed hepatic or renal function.

After the initial nausea and pain have disappeared, the patient is given a diet low in salt, saturated fatty acids, and calories and abundant in fruit juices. There should be no fixed rule regarding the duration and rigidity of restriction of activity, the program depending on the severity of the illness. When the condition of the patient permits, often after a few days, he may be allowed to sit up in a chair, use a bedside commode, or even walk a few steps to an adjoining toilet. A mild laxative may be necessary to prevent straining, a particularly harmful form of exercise. Sedatives, such as the barbiturates or reserpine, may be useful, and the latter may exert a further beneficial effect by slowing the heart rate and reducing an elevated pressure. During the period of bed rest, active movement of the legs should be encouraged to minimize the likelihood of phlebothrombosis, and elastic stockings are also useful for this purpose. If the patient's progress is satisfactory, he is permitted to walk about the room after 10 to 14 days, gradually increasing the activity until he is fully recovered.

Congestive Failure. Congestive failure usually takes the form of pulmonary edema. If dyspnea is severe and if digitalis has not been recently taken, lanatoside C (Cedilanid) 0.8 mg may be given intramuscularly or intravenously, following which another dose of 0.4 mg in 2 to 4 hr may be given once or twice. The patient should be constantly observed for the appearance of arrhythmias or nausea. Once congestive failure has been controlled, parenteral doses of the same drug 0.4 mg may be given daily for a few days; or one can change to an oral preparation such as digoxin 0.25 mg t.i.d. (to allow for the rapid excretion of lanatoside C) for 2 to 4 days, reducing to a maintenance dose of 0.25 to 0.5 mg per day. Other procedures employed in the management of congestive failure are discussed in Chap. 249.

Shock. By shock we mean not only a fall of blood pressure below 100 mg Hg, with a pulse pressure of 20 mm Hg or less, but also the accompanying cool, clammy skin, ashen color, apathy, lassitude, and diminished urinary output. Without these manifestations indicative of intense sympathetic activity and inadequate perfusion pressure, blood pressures as low as 90/60 require no treatment. Shock is a grave complication, usually but not necessarily co-existing with pulmonary edema. Pressor amines (p. 1395) and oxygen by mask or nasal tube should be given, as well as digitalis (p. 1383) if signs of left ventricular failure are elicited. When pressor amines are administered, one should be particularly careful to watch for the development of arrhythmias, particularly those of ventricular origin.

Arrhythmias. The management of the arrhythmias is discussed in Chap. 250. The most serious arrhythmias are the ectopic tachycardias: uncontrolled atrial flutter and fibrillation, because of the increased work and diminished coronary flow in an already badly damaged heart; ventricular tachycardia is even more serious since it carries the additional risk of developing into ventricular fibrillation. The serious forms of heart block are dangerous because of the likelihood of ventricular standstill or fibrillation. Even when bundle block alone develops, the mortality increases, probably because the ventricular contraction becomes less efficient. Ventricular premature beats are potentially hazardous because they may be the forerunner of a dangerous or fatal tachycardia or fibrillation. While the question is still controversial and the evidence indecisive, some believe that quinidine sulfate, 0.2 Gm four times a day, should be given to all patients as a prophylactic measure and certainly should be given when ventricular premature beats occur, provided heart block is not present.

Thromboembolic Episodes. The best treatment is prophylaxis: anticoagulants, elastic bandages for the legs, permitting the patient to take a few steps each day provided he is able to make this effort, and frequent active movements of the legs when the patient is confined to bed.

Rupture of the Heart. Transmural rupture and rupture of a papillary muscle are not amenable to therapy, since death usually occurs so rapidly. Occasionally, a patient suffering from interventricular septal rupture may survive for weeks or months, in which case corrective surgery may be possible. It is advisable to administer vitamin C if there is any question about the adequacy of the patient's diet prior to the infarction.

Shoulder-Hand Syndrome. It is possible that encouragement of the use of the muscles of the shoulder girdles shortly after the onset of the infarction may have some value as a means of preventing this syndrome. For the milder forms, including those

paroxysmal nocturnal dyspnea or of acute pulmonary edema. These attacks may seem to be the first manifestation of congestive failure; practically always, however, the patient has already experienced at least mild exertional dyspnea and may also have noted slight ankle edema at the end of the day (p. 1382). Physical examination reveals the manifestations of left ventricular hypertrophy, the most characteristic being the localized thrusting, forceful apex beat, enlargement of the heart, accentuation of the aortic second sound, and often pulsus alternans. With failure, actual or impending, a diastolic gallop rhythm is frequently heard. Eventually, provided the patient does not succumb during an attack of acute pulmonary edema, left ventricular failure progresses to the complete picture of congestive failure.

Treatment. The management of hypertensive heart disease consists essentially of the treatment of hypertension (p. 1355) plus the usual treatment of congestive failure (p. 1384) or of angina pectoris (p. 1447), according to which of these conditions exists.

SYPHILITIC HEART DISEASE

With rare exceptions, syphilitic disorders of the heart are secondary to involvement of the aorta (p. 1366), and the following discussion is concerned only with such aspects as affect the heart directly. Barring the unusual instance of gumma of the myocardium, syphilitic heart disease is primarily a problem of aortic insufficiency (p. 1435) when the luetic aortitis involves the aortic leaflets, as is usually the case. Occasionally, ischemic heart disease (p. 1444) occurs when a coronary ostium is occluded.

Clinical Course. The patient may reveal the fully developed signs of aortic insufficiency for years without suffering any symptoms, but once the latter develop, the progress of the patient is usually rather rapidly downhill. Acute left ventricular failure with paroxysmal nocturnal dyspnea is sometimes the earliest manifestation, though usually following slight but hardly noticeable exertional dyspnea and edema. When failure occurs, management is usually effective at first but often futile at the end of 1 to 3 years. When a coronary ostium closure takes place, the absence or presence of symptoms will depend on the completeness with which the compensatory collateral circulation follows. Often no symptoms develop, but when the collaterals are inadequate, angina or even myocardial infarction will ensue. Since ostial occlusion occurs so commonly in conjunction with free aortic regurgitation, which also impairs coronary flow (p. 33), it is difficult to know in any one patient how much the ischemia

is due to the regurgitation alone and how much to the coronary obstruction. Certainly one has good reason to suspect syphilitic coronary ostial occlusion when ischemic heart disease occurs in a young person with a positive serologic test for syphilis.

Treatment. The treatment of the failure is identical with that of congestive failure in general (p. 1385). Once the valvular disease is discovered, and particularly when failure has already occurred, the value of antisiphilitic therapy is dubious. In any case, such therapy should be administered with great caution, as a Herxheimer reaction causing complete occlusion of a coronary ostium may be disastrous (p. 1070).

HIGH-OUTPUT FAILURE

Diseases which alter the oxygen tension or the metabolism of the tissues, disorders which lead to arteriovenous communications, and certain hypervolemic disturbances may cause increase in the venous return to the heart and thus eventually produce "high-output failure." The pathophysiology of these conditions has been discussed in some detail (p. 99). Here we are concerned with the clinical picture. The recognition of these disorders is of great practical importance because most of them are amenable to specific treatment. Such recognition depends on the specific manifestations of each of these several diseases and also on the evaluation of these circulatory phenomena which, being directly related to the increased flow of blood, are likely to be found in all the high-output disorders.

Palpitation, fatigability, and "nervousness" are common complaints. Tachycardia is usually present and occasionally is pronounced. The pulse is full with a rapid rise and fall, and the pulse pressure is elevated. The skin is warm and usually moist.

A quick lift is usually present in the left parasternal area and may be confused with the more sustained heave of right ventricular hypertrophy. The heart sounds are usually loud but do not have the high-pitched staccato quality so characteristic of the first sound in mitral stenosis. Systolic murmurs may be heard at the mitral, aortic, and especially the pulmonic areas. They are of the ejection type and do not replace the first sound. The combination of diastolic gallops with split first or second sounds is common and may lead to a mistaken impression that an opening snap, filling rumble, or presystolic rumble is present.

It should be noted that these peripheral phenomena are similar to those of aortic insufficiency, while the cardiac findings mimic those of mitral stenosis. The presence of such a complication should always lead to the search for one of the high-output disorders. Before discussing the more common and

255 MISCELLANEOUS AND RARE CAUSES OF HEART DISEASE

William H. Resnik and
T. R. Harrison

HYPERTENSIVE HEART DISEASE

The problem of hypertension is examined in Chap. 245. The present discussion deals only with the heart disease resulting from hypertension. It is caused by the increased work of the left ventricle contracting against a permanently increased arteriolar resistance, leading to left ventricular hypertrophy of lesser or greater degree, in some instances so slight as to be clinically undetectable and insignificant.

Clinical Course. Following the development of hypertension, a number of years may elapse, 10 or 20 or even 30, before symptoms referable to the heart occur, if they develop at all. Since coronary sclerosis is a frequent accompaniment of hypertension, the clinical picture may be that of angina pectoris or myocardial infarction, with or without congestive failure. In others, congestive failure alone ensues, uncommon before the age of forty, becoming increasingly frequent with advancing years. The age at which the heart begins to fail depends on a number of variables: the level of the mean arterial pressure, the extent of myocardial scarring due to coronary sclerosis, and the degree of involutionary change (p. 1378) being the most important. It is not uncommon to observe individuals who have sustained levels as high as 240 systolic and 120 diastolic for many years and who have led active, unrestricted lives without ever experiencing any symptoms indicative of diminished cardiac reserve. Because the strain is primarily on the left ventricle, left-sided failure, with rise in pressure in the left atrium and consequent pulmonary engorgement, may set in suddenly and produce attacks of

The Heart in Anemia

Pathologic Physiology. In chronic anemia, when the hemoglobin falls to about 7 Gm or less, tissue hypoxia leads to a decline in peripheral resistance, increased cardiac output, and tachycardia. Since oxygen extraction in the coronary circulation is already practically maximal even in the normal person, myocardial oxygen requirements in anemia can be met only by increased coronary flow due to coronary dilatation. Fallor is usually greater than one anticipates with a given degree of anemia, and this is caused by the vasoconstriction in the skin, the blood being diverted to more important tissues. There is also a compensatory shunting of blood from the kidneys, but the glomerular filtration rate remains normal. It is the continued effect of the sustained increase in cardiac output and the inability of the coronary bed to expand beyond a certain limit that are responsible for the ultimate failure that may develop in some instances of severe anemia—another example of high-output failure. Congestive failure is especially likely to occur when cardiac reserve is already compromised by the involutory changes of age or by concomitant heart disease. Apparently some individuals with severe and long-standing anemia are able to compensate for the impoverished blood sufficiently well so that they engage in fairly strenuous physical work, even in a tropical climate. On the other hand, there are other patients with severe anemia who display failure without tachycardia or the clinical signs of increased cardiac output. The reasons for the absence of these compensatory mechanisms are unknown.

Clinical Picture. The clinical picture is that of high-output failure with anemia. Cardiac enlargement, occasionally with hypertrophy; unusually pronounced systolic murmurs because of the combined effects of decreased viscosity, increased flow, and dilatation of the mitral ring; rarely an early diastolic rumble at the mitral area due to increased flow or an aortic diastolic blow, presumably due to dilatation of the aortic ring, may present a confusing problem of diagnosis. Thus, when slight fever is also present, subacute bacterial endocarditis may be mimicked. In patients with sickle-cell anemia with fever and joint pains, acute rheumatic fever may be suspected.

With an organic obstruction in a coronary artery, thus nullifying the compensatory increase in coronary flow that would otherwise take place in anemia, angina may appear in a person with subclinical coronary sclerosis, or anemia may aggravate an already existent angina.

Treatment. The treatment is primarily that of the anemia, which naturally depends on the cause, and of the usual means of managing congestive heart failure. If it is deemed necessary to transfuse,

only red cells, free from plasma, may be given in small daily doses.

Thiamine Deficiency (Beriberi Heart Disease)

Thiamine deficiency (p. 545) leads to a derangement of carbohydrate metabolism the effects of which are similar to those caused by hypoxia, all the tissues including the myocardium being involved. This disturbance in myocardial metabolism, to which is added a further interference of fatty acid catabolism due to the deficiency of coenzyme A, results in impaired myocardial energy production. The defect in the peripheral tissues causes a peripheral vasodilatation, increased venous return and cardiac output, and consequently an increased load on a heart already handicapped by the metabolic defect. Clinical and experimental evidence indicate that cardiac failure is more prone to occur in persons who have the least involvement of the nervous system and a greater capacity for work and, hence, a greater opportunity for increased load on the heart.

The usual clinical picture of beriberi heart disease as seen in the Orient and described by Wenckebach and by Keefer is characterized by an enlargement of the heart, absence of arrhythmia, predominant failure of the right ventricle, bounding arterial pulsations, and the classical phenomena of high-output failure. This picture is rarely encountered in the occidental countries; the more common one is that of an individual who has been on a clearly deficient diet over a long period of time (excessive consumption of alcohol is almost invariably the cause), who has heart disease of uncertain origin, failure that does not respond to the usual methods of treatment, signs of mild peripheral neuritis or of other manifestations of dietary deficiency, and whose heart failure and cardiac enlargement disappear with the administration of thiamine. The electrocardiogram reveals only non-specific abnormalities. Not all patients respond quickly, spectacularly, and completely to thiamine treatment, and there is still disagreement as to whether thiamine deficiency can lead to irreversible myocardial changes.

It is evident that the diagnosis depends mostly on securing a good dietary history and on response to treatment. One should be particularly suspicious when high-output failure is observed. One should also bear in mind that the factor of thiamine deficiency may be playing a contributing role in all alcoholics who may have failure ostensibly due only to one of the more common forms of heart disease.

Arteriovenous Fistula

The acquired type of this disorder is usually the result of a penetrating injury, such as a knife or

important of these conditions, it should be emphasized that, when one of them is undoubtedly present, the diagnosis of organic disease of the mitral valve should be made with great reluctance. When one thinks that both conditions are present, it is well to defer judgment until the cause of the high-output syndrome has been found and removed. This will result in many instances in disappearance of those signs previously attributed to mitral disease.

Thyrotic Heart Disease

Heart disease caused by hyperthyroidism may present itself in the form of congestive failure, or angina pectoris, or atrial fibrillation, or in any combination of these disorders. It is uncommon before the age of forty, usually occurring in individuals who already suffer from some other form of heart disease but not at all infrequently in persons who, after cure of the hyperthyroidism, display no recognizable cardiac abnormalities. Moreover, autopsies on patients dying of thyrotic heart disease have confirmed the fact that hyperthyroidism alone may cause failure and death. Histologic examination of these hearts reveals no consistent type of lesion, in some no abnormalities being present, in others, rather insignificant fatty infiltration, myocardial necroses, or interstitial myocarditis. There is no basic difference between the influence of toxic nodular thyroid and toxic diffuse thyroid disease on the heart.

Pathologic Physiology. The fundamental derangement is the increased load imposed on the heart by the augmented bodily oxygen requirements in which the heart, itself, participates and the necessity for increased heat loss. Because of the increased skin and peripheral blood flow, peripheral resistance is diminished, arteriovenous difference is narrowed, cardiac output and heart rate are increased, the work of the heart increases because of the enhanced volume and rate loads, and the heart hypertrophies. In addition, it is possible that increased catecholamines demonstrated in the myocardium of experimentally induced hyperthyroidism in dogs may interfere with myocardial enzyme action and energy production as well as contributing to myocardial hypoxia. When failure finally ensues, the resting cardiac output falls from its previously elevated levels, increasing or not with exercise depending on the cardiac reserve; but even in failure, the cardiac output and stroke volume are often higher than the same functions in a resting euthyroid individual without failure. In other words, thyrotic heart disease with failure represents a typical form of high-output failure. The load resulting from the overactive thyroid is well tolerated by the young and healthy heart. It is when this load is superimposed on the heart already affected by involutionary changes (presbycardia), and par-

ticularly when cardiac reserve has been diminished by some other form of heart disease, that thyrotic heart disease manifests itself. Angina pectoris occurs only in those who already have a lesion predisposing to myocardial ischemia, such as coronary sclerosis or aortic stenosis, and the increased load serves merely to raise a subclinical condition to the clinical level.

Clinical Manifestations and Course. In some persons, the characteristic features of hyperthyroidism are so conspicuous even after the development of failure that the diagnosis is simple. In others, when the eye phenomena and thyroid enlargement are not striking and other classic manifestations of thyrotoxicosis are obscured and masked by the antagonistic effects of cardiac failure, it is not surprising that the basic overactivity of the thyroid is hardly discernible. Nevertheless, thyrotoxicosis should be suspected as a contributing factor in patients with cardiac disease under the following circumstances: persistent tachycardia that endures after prolonged rest and during sleep, any suggestion of high-output failure (p. 1377) in the absence of other recognizable causes, failure of the usual measures in the management of failure to bring about a satisfactory response. Attacks of paroxysmal atrial fibrillation or the presence of chronic atrial fibrillation in a person without mitral stenosis, particularly when the ventricular rate is resistant to the slowing effect of full doses of digitalis, should be especially suspected, since atrial fibrillation occurs in approximately 60 per cent of patients over the age of forty-five with hyperthyroidism.

After treatment has been instituted and thyrotoxicosis eradicated, remarkable improvement in a previously intractable form of heart disease usually follows. About one-third of those with fibrillation revert spontaneously to a normal sinus rhythm; angina and congestive failure disappear or become easily controllable.

Diagnosis. Estimations of the basal metabolic rate and of the serum cholesterol are subject to so many influences unrelated to the activity of the thyroid that they are of little value. A circulation time that is within the normal range in a person suffering from congestive failure is highly suggestive of some type of high-output failure; but the most reliable methods of diagnosis are the determinations of the protein-bound iodine of the plasma and of radioiodine studies, provided one bears in mind the sources of error even in these procedures. Finally, the diagnosis should be confirmed by a favorable response to therapy directed at the hyperthyroidism.

Treatment. The management of thyrotic cardiac disease is that of heart failure but primarily that aimed at eradication of the hyperthyroidism (p. 591).

not encountered. However, in certain well-defined disorders, such as rheumatic fever, diphtheria, scrub typhus, Chagas disease, the involvement of the heart may be clinically important and even fatal. There are other instances, both with an acute and also with a chronic course, in which myocardial failure seemingly develops without cause and when, in such a case, a more or less diffuse inflammatory lesion is confined to the myocardium, all other evidences of a related infection or other disorder being absent, the condition has commonly been designated *isolated* or *Fiedler's myocarditis*. Viral studies have indicated, however, that at least in some the myocarditis has been caused by strains of Coxsackie or of influenza virus. In other instances, such as primary atypical pneumonia, the coexistence of myocarditis with the pulmonary disorder constitutes indirect evidence that the same agent is responsible for both. In some of these various disorders, pericarditis has also been present. Some investigators believe that these forms of chronic myocarditis, of known or of as yet unidentified viral origin, may be responsible for "endocardial fibroelastosis," "idiopathic ventricular hypertrophy," and for some of the cases of "post-partum heart disease." The failure to recognize the relationship of the myocarditis to a respiratory infection may come from the fact that several weeks may elapse before the onset of the cardiac manifestations. The clinical picture may be that of a fulminating and rapidly fatal form of cardiac failure or of a slowly developing course, extending over a period of years and characterized by enlargement of the heart, arrhythmias, and eventually failure. When, during or shortly after a respiratory infection, clinical signs of cardiac complications are absent and the only manifestations are such electrocardiographic changes as prolongation of the P-R interval or T-wave alterations, complete recovery nearly always occurs.

TRAUMATIC HEART DISEASE

Cardiac damage may be due to both penetrating and nonpenetrating injuries, the most frequent cause of the latter being impact of the chest against the steering wheel of a motorcar. Serious injury of the heart may ensue though there is no external sign of disease.

Although the common type of injury is myocardial contusion, any structure of the heart may be affected. The valve cusps may be ruptured, and the appearance of a loud murmur in a previously healthy person is followed by rapidly progressive myocardial failure. A coronary artery may be lacerated, leading to fatal tamponade. The frequency of coronary thrombosis after coronary injury is uncertain. It is usually accepted that the relationship

between coronary thrombosis and infarction and a preceding injury is uncertain or unlikely if the former occurs more than 2 to 3 days after the trauma. Myocardial contusion may cause arrhythmias, bundle branch block, or electrocardiographic abnormalities resembling those of infarction. The most serious consequence of nonpenetrating injury is rupture of either of the atria or ventricles, which is always fatal; rarely, a patient with ruptured ventricular or auricular septum may survive. It is important to bear in mind trauma as a cause of otherwise unexplained electrocardiographic changes (Fig 254-3). Hemopericardium with tamponade may follow tear of the myocardium or of a pericardial vessel or of a coronary artery.

Treatment for myocardial failure due to valve rupture is rarely effective. If the electrocardiographic abnormalities are those of infarction, it is impossible to distinguish between contusion and infarction secondary to coronary artery injury; in any case, treatment is the same and is that accorded the patient with infarction. Pericardial tamponade has been managed successfully by repeated taps alone. Others recommend operation when tamponade recurs rapidly or when bleeding takes place into the thoracic or abdominal cavity. Pericardial hemorrhage may be followed by permanently inverted T waves and occasionally by constrictive pericarditis.

The electrocardiographic changes that may follow myocardial contusion are of no significance unless accompanied by clinical manifestations. However, their confusion with similar changes following infarction may make it difficult or impossible for the patient to secure life insurance.

MALIGNANT CARCINOID

The cardiac manifestations of this disorder are considered in Chap. 90.

HEART DISEASE OF OBSCURE ETIOLOGY

Occasionally the physician is confronted by a form of heart disease that does not appear to belong to any of the more common categories previously described, and he is obliged to consider more unusual types of heart disease. Before embarking on a speculative voyage in search of some esoteric kind of cardiac disease, he should give thought again to the possibility that an ordinary type may actually be present. Aortic or mitral stenosis may be missed because the characteristic murmurs are absent as a result of diminished cardiac output, especially in failure. The various forms of hyperkinetic heart disease are often forgotten if one has ignored the manifestations of the overactive heart. The most frequent in this group is the thy-

bullet wound. Congenital fistulas, usually multiple, also occur.

Pathologic Physiology. The initial effect of the leakage is a reduction of effective blood volume by the amount of blood that leaks into and is sequestered in the involved extremity. This promotes increase in total blood volume. The fall in blood pressure leads to an increase in heart rate and a generalized vasoconstriction. Nevertheless, despite the peripheral vasoconstriction, the total peripheral resistance is diminished because of the predominant effect of the leakage. Renal vasoconstriction causes a fall in glomerular filtration rate but an increase in filtration fraction (p. 183), and this plus increased tubular sodium reabsorption leads to an increased extracellular volume. In turn, this raises the cardiac output, mediated through a moderate tachycardia and elevated stroke volume (increased systolic emptying against a lowered peripheral resistance). Eventually, the heart fails when the myocardium is incapable of coping with the burden of the sustained elevation of cardiac output.

Symptoms and Diagnosis. The diagnosis of arteriovenous fistula is not difficult if one keeps the possibility in mind. The swelling and increased warmth in the vicinity of the fistula, the continuous murmur with systolic accentuation, usually associated with a thrill, the enlargement of the heart with the bounding pulse, the slowing of the heart when the fistula is compressed (Branham's sign) constitute a characteristic clinical picture. When myocardial failure develops, the features are those of the high-output type. Even if an arteriovenous fistula is not immediately apparent, cardiac failure with outspoken signs of aortic insufficiency without the murmur of that lesion should lead to a careful inquiry into possible injuries and wounds and the search for a fistula. Since extensive Paget's disease causes heart failure on essentially the same basis because of the development of innumerable arteriovenous fistulas in the abnormal bone, it should also be borne in mind under these circumstances.

Pulmonary arteriovenous fistulas may be congenital (p. 1534) or acquired. They may produce cyanosis, polycythemia, and clubbing of the fingers and thus mimic the cyanotic forms of congenital heart disease. However, the heart is usually normal or may show slight enlargement.

The Heart in Acute Nephritis

The edema and the congestive phenomena of acute glomerulonephritis probably depend on several mechanisms. The peripheral resistance may be increased, but more important is the primary retention of sodium which then causes an increase in plasma volume and a hyperkinetic (high-output) state (p. 1379). This is what has been termed "non-cardiac circulatory congestion" and would account

for the usually inconspicuous lengthening of the circulation time and the absence or minimal engorgement of the lungs and liver, despite the increased venous pressure. Nevertheless, one does occasionally encounter patients in whom the circulation time is definitely prolonged, the congestive phenomena resemble those of myocardial failure, and who display a prompt improvement with diuresis after digitals. How much this failure of the myocardium depends on the increased work load of the heart and how much to an obscure effect of the disorder on the myocardium is not known.

THE HEART IN MYXEDEMA

The hypercholesterolemia associated with myxedema favors the development of coronary sclerosis and angina. In addition, myxedema may be complicated by pericardial effusion that rarely, if ever, causes tamponade. Finally, myxedema may produce electrocardiographic changes with prolonged PR conduction time and lowered voltage, although it is dubious whether myxedema ever causes actual myocardial failure. The dramatic decrease of the cardiac silhouette and the disappearance of the electrocardiographic abnormalities are usual after the administration of thyroid extract. However, it should be given with great caution in persons with myxedema because of the possibility of inducing anginal attacks or psychic disorders, when sclerotic vessels inhibit increase in blood flow parallel with the rising oxygen need of the heart and brain.

POST-PARTUM HEART DISEASE

Whether such a specific entity exists is a debatable subject. The term has been applied to cardiac disease of unknown etiology, presumably related in some way to pregnancy, for the reports in the literature indicate that symptoms usually appear 2 to 6 weeks after the termination of pregnancy, occasionally a short time before the termination. The heart enlarges, there are no characteristic murmurs or irregularities, gallop rhythm is common, as are pulmonary and systemic emboli. Response to treatment is unsatisfactory, and the prognosis has varied in different accounts. If one excludes those cases which are related to toxemia of pregnancy, to embolism (p. 1538) and to postinfectious myocarditis, one gains the impression that a specific form of heart disease, somehow related to the post-partum period, is a very rare entity, if it exists at all.

MYOCARDITIS

Almost any acute generalized infectious disease may cause inflammatory changes in the myocardium, but ordinarily significant clinical findings are

Familial cardiomegaly is a term that has been applied to cardiac disorders of undetermined origin occurring in two or more members of a family. Review of the literature indicates wide differences of age distribution, clinical characteristics such as rapidity of progression, presence or absence of endocardial thrombi, frequency of sudden death and, finally, in the histologic appearance of the myocardium. Evidently, the designation familial cardiomegaly must embrace several distinct disorders.

Neoplasms of the Heart. With the exception of myxoma of the left atrium, primary tumors of the heart (rhabdomyoma, mesothelioma of the pericardium, a variety of other benign tumors or their malignant counterparts) are medical curiosities. *Myxoma of the atrium*, usually of the left, is rare but should not really be considered in a discussion of heart disease of obscure origin, because almost invariably it, like ball valve thrombus, is usually diagnosed as mitral stenosis and recognized first at operation. Occasionally, however, attention to certain striking features may lead to correct diagnosis before operation: variability of the murmur of mitral stenosis with change of position, syncope, paroxysms of acute pulmonary edema—all caused by sudden and intermittent obstruction of the mitral orifice.

Secondary tumors of the heart are much more frequent and have been reported as occurring in 10 to 20 per cent of cases of malignancy. The most common form is by direct extension to the pericardium of a primary carcinoma of the breast or bronchus, malignant thymoma, or lymphoma. The clinical picture is that of rapidly recurring pericardial effusion, usually bloody. Metastases to the myocardium are rarely responsible for symptoms or signs that permit recognition, although suspicion should be aroused when the development of intractable failure or a distinctly abnormal electrocardiogram takes place in a person known to harbor other metastatic lesions and previously free of heart disease.

Geographic factors are sometimes of importance in determining the cause of heart disease of obscure origin. Residents in areas where *Schistosomiasis mansoni* is endemic should bring to mind the possibility that this disease may cause cor pulmonale, while cardiac trypanosomiasis (*Chagas disease*) should be considered in persons living in northern and central South America. In the Orient, heart disease due to scrub typhus is encountered.

For the sake of simplicity of presentation, these various unusual diseases of the heart have been classified as involving primarily the endocardium or myocardium or pericardium. Clinically these distinctions will rarely be apparent, nor will these disorders differ very much from the heart disease and

failure that occur in about 10 per cent of cases of advanced cirrhosis of the liver and are attributed to the increased cardiac output that has been demonstrated in this disease. When sarcoidosis or amyloidosis or cirrhosis of the liver or malignant disease of the mediastinum, to name but a few, is known to be present or strongly suspected, there is a logic in assigning cardiac disease of otherwise undetermined origin to the respective disorder. But when definite clues or biopsy proof is lacking, the diagnosis of many of these rare forms of heart disease can hardly be anything other than a lucky guess, the artificial by-product of the clinical pathologic conference atmosphere. One cannot help gaining the impression that a lengthy and seemingly scholarly differentiation under these circumstances can only be "a tale . . . full of sound and fury, signifying nothing."

Since cure or significant amelioration of certain forms of heart disease is now possible, they must always be borne in mind when an obscure form of heart disease is considered. One should never fail to search carefully for subacute bacterial endocarditis, the various hyperkinetic circulatory states, certain types of congenital and acquired valvular heart disease, constrictive pericarditis, and cor pulmonale due to thromboembolic disease.

rototic heart which may be so masked by congestive failure that the customary clues are largely obliterated. In a person beyond forty-five or fifty years, congenital heart disease is likely to be forgotten, and patent atrial septum, which is the one form of congenital heart disease that is most likely to go on to old age, may be ignored. In younger persons, the development of pulmonary hypertension with Eisenmenger's syndrome may abolish the gradients of pressure responsible for the typical murmurs of patent ductus, atrial and ventricular septal defect, with the result that a common form of congenital heart disease will be undetected. Chronic constrictive pericarditis and chronic pericardial effusion are other disorders that are important to keep in mind since they are often curable.

It should be evident that the question of obscure heart disease arises when the patient presents no significant murmurs, hypertension, pulmonary disease, outspoken signs of hyperkinetic heart disease, or unequivocal coronary disease (angina pectoris or myocardial infarction). When the situation arises in an older person, it is hardly ever considered a problem, since this kind of case is almost automatically labeled "arteriosclerotic heart disease." However, it has been pointed out previously that the statistical frequency of coronary disease should not exclude the consideration of other nonvalvular, normotensive forms of heart disease. Moreover, exactly the same problem appears in younger persons, although coronary disease is not so likely here to interfere with the contemplation of other possibilities. In both young and old, one should bear in mind that many instances of heart disease of apparently obscure etiology are simply unrecognized examples of common heart disease. If these can be reasonably excluded, one is then forced to speculate on the possibility or probability that an unusual kind of heart disease may actually be present.

Disorders Affecting the Mural Endocardium. This group of disorders of unknown etiology and pathogenesis constitutes one of the most confusing fields in cardiology. These disorders have certain superficial anatomic features in common, but careful morphologic study reveals sufficiently significant differences between them to make it likely that they represent diseases of varying origin. It is uncertain whether any of them are related to obstruction of cardiac lymphatic drainage, which has been shown to produce similar anatomic changes in dogs.

In this country and in a few reports from Europe, there has been described a condition known as *idiopathic hypertrophy of the heart or subendocardial fibrosis*. Because a number of these patients had been chronic alcoholics and had suffered from long-standing malnutrition, it has been suggested that the heart disease represents the end stage of

thiamine deficiency, a view that has not been generally accepted. Mural thrombosis is a characteristic finding, and the usual clinical picture is that of enlargement of the heart, systemic embolic manifestations, arrhythmias, progressive failure of the heart unresponsive to digitalis or vitamin therapy. *Endocardial fibroelastosis* occurs most frequently in infants, but adults may be afflicted. At autopsy, marked hypertrophy of the heart, more or less generalized thickening of the endocardium, chiefly of the left ventricle, and frequently mural thrombi are found. The clinical picture is similar to the one described above. In a very few instances, typical angina pectoris has been present, although coronary sclerosis has been absent at autopsy. Some very competent pathologists are convinced that this disease, in adults at least, is a result of chronic myocarditis, since transition stages between the two can be demonstrated. An identical clinical picture, with *endocardial fibrosis and subendocardial necrosis* has been described in South Africa (Becker's disease), and another variant is *endocarditis fibroplastica with eosinophilia* (Loeffler's disease), reported from Western and Central Europe and very rarely encountered in Great Britain and the United States. From Uganda and other parts of tropical Africa have come reports of *endomyocardial fibrosis*, again with somewhat similar manifestations except that mural thrombi and systemic emboli are quite infrequent whereas pericarditis is often present.

Disorders Affecting the Myocardium. The recognition of cardiac involvement by *sarcoidosis*, *scleroderma*, *hemochromatosis*, and *amyloid disease* will depend on the demonstration of these disorders elsewhere in the body by biopsy or by other precise methods. All these diffuse disorders of the myocardium, as well as an occasional instance of diffuse fibrosis secondary to coronary disease, may present the clinical and hemodynamic characteristics of chronic constrictive pericarditis. *Van Gierke's disease*, *Friedreich's ataxia*, *muscular dystrophy*, and *trichinosis* are other diseases that may be associated with myocardial involvement. *Hurler's syndrome* is frequently responsible for lesions in the valves, especially the mitral and aortic, as well as in the myocardial cells and coronary arteries. *Disseminated lupus* is very frequently complicated by pericarditis and occasionally by signs of valvular disease; *polyarteritis nodosa* is often associated with coronary involvement, myocardial disease, or pericarditis.

The combination of marked eosinophilia with clinical or electrocardiographic evidence of myocardial injury should arouse the suspicion of *polyarteritis*, *trichiniasis*, *eosinophilic leukemia* with infiltration of the heart, or *Loeffler's fibroplastic endocarditis*.

256 PERICARDITIS

William H. Resnik and
T. R. Harrison

Pericarditis may be classified according to two different methods, both of practical importance.

CLASSIFICATION

I. Morphologic and clinical classification

A. Acute

1. Fibrinous
2. Pericardial effusion

B. Chronic pericardial effusion

C. Chronic constrictive pericarditis

II. Etiologic classification

A. Infectious

1. Acute benign
2. Tuberculous
3. Pyogenic
4. Mycotic (fungous infection)

B. Noninfectious

1. Ischemic (acute myocardial infarction)
2. Uremic
3. Neoplastic
4. Myxedematous
5. Traumatic
6. Anticoagulant therapy

C. Uncertain etiology

1. Rheumatic
2. Disseminated lupus erythematosus and other collagen diseases
3. Post-cardiac-injury syndrome
 - a. Post-myocardial-infarction syndrome
 - b. Postpericardiotomy (postcommisurotomy) syndrome
 - c. Posttraumatic syndrome

General Comments. The above classification implies that not only must one determine whether or not pericarditis is present, with or without effusion or constrictive scar, but one must also seek to determine the cause.

Pain is an important symptom in various forms of pericarditis, usually being present in the acute infectious types and also in those forms enumerated under "uncertain etiology." Pain, however, is often absent in a slowly developing tuberculous or neoplastic pericarditis, and it is usually absent in the pericarditis of myocardial infarction. Pain rarely constitutes an important complaint in uremic pericarditis, probably because of the stuporous or comatose state of the patient. The character of the pain has been described in a previous chapter (p. 36). Any one or combination of the three components of pericardial pain may occur, but usually the predominant one is the pleuritic type of pain. Occasionally the steady, constrictive pain, radiating into either or both arms and identical with the pain of

ischemia, may overshadow the pleuritic pain, or it may occur alone at the onset of the illness, with the result that confusion with myocardial infarction is not infrequent. This problem becomes even more perplexing when, with acute pericarditis, the serum transaminase rises to levels of about 80 units but occasionally to 125 to 135. Moreover, shock may appear, the mechanism being uncertain. Possibly in some instances it may be caused by the same obscure reflexes that play a part in the shock of myocardial infarction; in other cases, it may be brought about by tamponade caused by the rapid development of pericardial fluid, too small in amount to be detected by x-ray. The location of pericardial pain has also been described (p. 38). Suffice it to say that a pain felt either in the precordium or in one or both shoulders or trapezius ridges and aggravated by inspiration should alert one to the possibility of an acute pericarditis.

The pericardial friction rub is the most important physical sign, sometimes elicited only when firm pressure with the stethoscope is applied to the chest wall. The pericardial rub is likely to be inconstant and transitory, and a loud to-and-fro leathery sound may disappear within a few hours, possibly to reappear the following day.

The electrocardiogram usually displays elevation of the S-T segments in several leads without reciprocal depressions in others and without significant changes in the QRS complexes. Later, the T waves become inverted, and in some instances this latter change is permanent.

Pericardial effusion is usually associated with an enlargement of the cardiac silhouette, and this is especially important when it occurs rapidly under observation. There is no definitive contour to the cardiac shadow in effusion, and differentiation from enlargement of the heart may be difficult. A very important bedside clue to the presence of effusion is the increase in the area of cardiac flatness (not dullness) on percussion, extending to the third left interspace and to the right of the midline of the sternum, with loss of the normal percussion resonance over the lower sternum. The heart sounds tend to become faint, but they may remain loud; the friction rub may disappear or remain clearly audible; the apex impulse may vanish but sometimes is felt well within the left border of dullness. On fluoroscopic examination, the ventricular pulsations are usually diminished or absent. When the effusion is large, one often encounters an area of dullness and tubular breath sounds at the angle of the left scapula, probably caused by compression of the lung (Ewart's sign). The importance of this finding comes from the fact that often the signs may be interpreted as being due to a pneumonic consolidation.

When an effusion develops, the fluid nearly al-

lous origin must be deemed a serious error. Consequently, no method of examination should be left undone to establish or rule out the diagnosis. This means chest films for pulmonary tuberculosis and a search for tuberculosis in other structures; tuberculin tests, repeated after several weeks; cultures and smears of gastric washings and of pericardial fluid. Finally, if the diagnosis is still obscure, one should resort to pericardial biopsy. If one is still unable to secure definitive evidence and one has good reason to be highly suspicious of the presence of tuberculosis, antimicrobial therapy is justified. Pericardiectomy with concomitant antituberculous therapy has been successfully employed if exploration reveals a thickened pericardium.

Differential Diagnosis of Chronic Pericardial Effusion

Cultures and smears of the pericardial fluid are so frequently negative in subsequently proved cases of tuberculous pericarditis, and a positive tuberculin test (p. 1006) so often found in persons who have no active tuberculosis, that one is sometimes faced with the dilemma of trying to decide how much emphasis to attach to each of these conflicting findings.

Myxedema may be responsible for a pericardial effusion that is sometimes massive. The other manifestations of myxedema should clarify the diagnosis, but unfortunately, even when they are present, the diagnosis is frequently overlooked. It is important, therefore, to make appropriate tests for thyroid function in every person with an enlarged cardiac outline of undetermined origin.

Neoplasms, disseminated lupus, rarely polyarteritis nodosa, mycotic infections, certain forms of endomyocardial fibrosis found in Africa, and very rarely, *severe anemia and scleroderma* may be the cause of a chronic pericardial effusion.

Finally, there are individuals who, without fever or other constitutional symptoms, are known to have had an "enlarged heart" for years, sometimes with, more often without, congestive failure, and who have subsequently been found to be suffering from a chronic pericardial effusion. The most exhaustive studies have failed to reveal the etiology of these effusions, but they have all been completely relieved by the establishment of a pleuropericardial window. Such disorders have been designated *chronic idiopathic pericardial effusion*, with full recognition that "idiopathic" merely signifies our present ignorance of the cause of these disorders. For example, one form of pericardial effusion, apparently "idiopathic," has been found to be caused sometimes by an *injury to the heart* following a non-penetrating blow to the chest, the relationship between the injury and the subsequent effusion being

obscured by the lapse of weeks before the effusion develops. This type of pericardial effusion is simply another form of the post-cardiac-injury syndrome.

CHRONIC CONSTRICTIVE PERICARDITIS

This disorder results when the healing of an acute fibrinous or serofibrinous pericarditis is followed by obliteration of the cavity of the sac, with the formation of granulation tissue which gradually contracts and forms a firm scar, encasing the heart and interfering with filling. The condition may be the result of tuberculous, staphylococcal, or pneumococcal infection, acute benign infectious pericarditis, traumatic pericarditis, but more often the cause is undetermined. Rarely, routine fluoroscopic examination may reveal calcification of the pericardium in an individual who is free of all symptoms referable to the heart. Usually, however, the clinical picture is characterized by dyspnea on exertion, which, however, is often relatively slight at rest, while orthopnea may be entirely absent; pronounced enlargement of the liver; distention of the cervical veins; ascites; and peripheral edema. The heart is normal in size in about half the cases; in others it is slightly to markedly enlarged. A paradoxical pulse is frequently encountered, and a protodiastolic gallop is present in most patients. Both by palpation and by x-ray, marked diminution in cardiac pulsation is noted. A very important finding is the presence of calcification of the pericardium, visible by x-ray in about one-half the cases. The spleen is sometimes palpable, and in the absence of evidence of bacterial endocarditis, splenomegaly in a patient with congestive failure should arouse suspicion of constrictive pericarditis. The electrocardiogram frequently displays low voltage and flattening or inversion of the T waves in all three limb leads. Atrial fibrillation is often present in this condition.

Congestive failure is initially the result of impaired filling of the ventricles caused by the restrictive action of the inelastic pericardium. However, the fibrotic process may extend into the myocardium, and congestive failure may then be due to the combined effects of the myocardial and the pericardial lesions. The interference with filling reduces the work of the heart, and myocardial atrophy may occur. This probably accounts for the delayed beneficial effects of operative treatment. Improvement may not become apparent until a number of months have elapsed. Presumably, the atrophy disappears when the impairment of filling is removed by resection of the pericardium. Because the filling of the right ventricle is impeded, this chamber is unable to flood the lungs with blood, acute pulmonary edema does not occur, and orthopnea is minimal.

S-T segment elevation soon being replaced by inversion of T in the same lead. Slight fever and/or an evanescent friction rub may or may not be observed. This syndrome is thus similar to the more usual varieties of fibrinous pericarditis but displays the following differences. (1) The electrocardiographic findings point toward focal rather than diffuse inflammation of the pericardium. (2) The clinical course is unusually mild. (3) Pericardial effusion does not occur to a detectable degree.

Pathologists have long recognized focal patches of pericardial thickening as incidental findings at necropsy and, because of the frequency in young men, have designated them as "soldier's patches." It is tempting to speak of the clinical picture described in the preceding paragraph as the *soldier's patch syndrome*, but if this is done there should be clear recognition that such a designation is based only on a logical inference and not on any proof that the clinical disorder mentioned is in fact the analogue of the anatomic finding.

Differential Diagnosis of Acute Fibrinous Pericarditis

Since there is no specific test for acute benign infectious pericarditis, the diagnosis is primarily one of exclusion. Consequently, before concluding that one is dealing with the disorder known as acute benign infectious pericarditis, one must consider all other disorders that may be associated with an acute fibrinous pericarditis.

Acute Myocardial Infarction. When an ischemic pericarditis gives rise to a pleuritic type of pain, confusion with an infectious form of pericarditis is possible and one must rely on the time of occurrence of fever and pain, electrocardiographic abnormalities, such as the appearance of Q waves, the extent of the transaminase elevations, and the total clinical picture. More common is the error of assuming that acute benign infectious pericarditis is an acute myocardial infarction (p. 1454).

Post-Cardiac-Injury Syndrome. The two disorders in this category that are likely to be confused with acute benign infectious pericarditis are the *post-myocardial-infarction syndrome* and the pericarditis that may follow a nonpenetrating bruise to the chest. When the pericarditis occurs within a few weeks or months after the infarction or the blow to the chest, one is justified in concluding that the two are probably related. However, it is known that many individuals suffer a completely symptomless infarct. When an acute pericarditis occurs in such a person and when there is no reason to suspect a previous infarction, differentiation between the post-myocardial-infarction syndrome and acute benign infectious pericarditis is impossible on clinical grounds. Subsequently, the development of angina

pectoris or acute infarction may then, in retrospect, clarify the nature of the previous illness. The conclusion to be drawn is that, in any person over the age of forty to forty-five, an apparently classical picture of acute benign infectious pericarditis may actually be the first overt manifestation of serious coronary disease. Similarly, a nonpenetrating chest-wall blow may be forgotten when the acute pericarditis develops several weeks later, and the relationship between the two may not be recognized. One must also bear in mind that the person who has sustained a myocardial infarct or a blow to the chest acquires thereby no immunity to the viruses that cause the infectious form of pericarditis and that, when we make the diagnosis of post-myocardial-infarction syndrome or pericarditis following a chest bruise, we are speaking in terms of probabilities and not certainties, until more precise methods of differentiation are available.

Pericarditis Due to Collagen Disease. Most important in the differential diagnosis is the pericarditis due to disseminated lupus, in which disease it occurs at some time in its course in over 50 per cent of the cases. Sometimes it appears as an asymptomatic effusion, but more often pain is present and very rarely tamponade may develop. When it occurs in the absence of other evidences of the underlying disorder, differentiation from acute benign infectious pericarditis or a mild form of *tuberculous pericarditis* may be made only on discovery of LE cells or by the specific methods of diagnosis of tuberculosis (p. 1007).

The pericarditis of *acute rheumatic fever* is always associated with evidences of severe pancarditis. *Pyogenic pericarditis*, usually secondary to pneumonia, is now far less common than before the advent of effective antibiotics. These conditions, as well as *uremic* or *neoplastic pericarditis*, should cause little difficulty of diagnosis.

CHRONIC TUBERCULOUS PERICARDIAL EFFUSION

Tuberculous pericarditis has been described in Chap. 146, Tuberculosis. The acute form has already been mentioned, and it needs to be stated here only that in other cases there may be no history of pain, the symptoms being those of infection in an individual with massive effusion, with or without manifestations of tuberculous involvement of other structures. It is important to bear this condition in mind when a middle-aged or elderly person with fever has what appears to be an enlarged heart of undetermined etiology, with or without congestive failure. Inasmuch as we now have effective specific methods of therapy that have reduced the mortality radically from the previous figures of 50 to 80 per cent, overlooking a pericardial effusion of tubercu-

pericarditis is responsible is by exploration of the pericardium.

OTHER DISORDERS OF THE PERICARDIUM

Tumors of the pericardium are almost always secondary to malignant neoplasms of the mediastinum. The most common primary sources are carcinoma of the bronchus or breast, lymphoma, and occasionally other malignancies of the mediastinum, such as thymoma. Rarely, the tumor may originate in the pericardium as a mesothelioma. The usual clinical picture is that of an insidiously developing pericardial effusion, often bloody, and the chief problem is differentiation from a tuberculous effusion.

Pericardial cyst appears as a rounded or lobulated deformity of the cardiac silhouette, the most common location being at the right cardiophrenic angle. Its only clinical significance lies in the possibility of confusion with tumor.

Section 3: The Kidneys

INTRODUCTION

T. R. Harrison and
Franklin H. Epstein

The patient with renal disease may exhibit any one of a wide variety of problems. These include headache, hypertension, edema, heart failure, anemia, and coma. Less overt but no less frequent presenting symptoms are lassitude, anorexia, nausea, and unexplained fever. The common causes and the differential diagnosis of these several phenomena have been considered in previous chapters. The reader is referred particularly to Chap. 20, which deals with disordered renal function.

Few instances of clinically significant bilateral kidney disease will be overlooked if the urine is examined routinely and carefully for protein. The evaluation of the degree of renal damage rarely requires elaborate tests and can usually be based on such simple measurements as the concentrating power, the excretion of phenolsulfonphthalein, and the urea content of the blood. The rate of progression of the disease can be determined only by serial clinical observation. In this respect, laboratory

tests may be misleading unless correlated with the patient's symptoms.

The physician should be continually alert to the possibility that certain curable but rare renal disorders may produce clinical pictures which are almost identical with those caused by more common but less treatable diseases. Thus he should consider the possibilities that hypertension may be due to unilateral renal disease (p. 1351) and that syphilis is a very rare but curable cause of the nephrotic syndrome. In a patient with renal insufficiency, the diagnosis of chronic uremia should not be entertained until such occasional but removable causes as obstruction, acute infection, shock, sodium or potassium depletion, congestive heart failure, tubular necrosis, or acute glomerulonephritis have been considered and excluded.

The discussion to follow is divided into two chapters. The first deals with general aspects of disorders of the kidneys and includes the treatment of chronic renal failure, which is a complication of a wide variety of different conditions. The second chapter is concerned with the specific diseases of the kidney and includes the management of acute renal failure, which has a smaller number of under-

Inasmuch as the usual physical signs of cardiac disease (murmurs, cardiac enlargement) may be inconspicuous or entirely lacking, the presence of hepatic enlargement and intractable ascites may lead to a mistaken diagnosis of cirrhosis of the liver. This error should be avoided if the neck veins are inspected carefully in all patients with ascites and hepatomegaly. *Given a clinical picture resembling cirrhosis but with the added feature of distended neck veins, careful search for calcification of the pericardium by chest films, with the patient in the oblique position, should be carried out and may disclose a curable or remediable form of heart disease.* Since calcification occurs in only about 50 per cent, exploration of the pericardium is justifiable if the clinical picture is suggestive enough.

The clinical picture described above represents the full-blown and classical disorder. It is important to bear in mind that sometimes a calcified pericardium, clearly visible by x-ray, may cause no symptoms whatsoever; or a patient may display symptoms of congestive failure without the classical features of constrictive pericarditis, and autopsy may nevertheless reveal the latter type of lesion.

Treatment. In the treatment of constrictive pericarditis, diuretic drugs and sodium restriction are useful. Digitalis, which is rarely of value in the preoperative state, may be beneficial in the prevention of heart failure when resection of the thickened pericardium permits an increased inflow into the ventricles and hence an enhanced burden on an atrophic myocardium. The benefits derived from cardiac decortication are often striking, and frequently the improvement, while slight at first, is progressive over a period of many months. The patient may be restored from a state of invalidism to something approaching normal activity.

Many instances of constrictive pericarditis are of tuberculous origin. Antituberculous therapy during the phase of effusion may prevent the development of constriction, and such specific therapy carried out before and after operation, if any tuberculous activity is present, will prevent the spread of the infection.

No treatment is required for those persons who are found to have a calcified pericardium but in whom there is no evidence of increased venous pressure.

Differential Diagnosis of Constrictive Heart Disease

There are two general problems in the diagnosis of constrictive heart disease. The first is the differentiation of the constrictive from the nonconstrictive disorders that lead to congestive failure. The second is the separation of constrictive pericarditis

from other forms of constrictive heart disease. The clinical picture caused by any of the forms of constrictive heart disease may not be so fully developed as to display the classical features described above, and one may not suspect that heart failure is being caused by one of these disorders. On the other hand, a nonconstrictive type of heart disease may simulate the constrictive forms: e.g., cor pulmonale may be associated with severe systemic venous congestion and with little or no pulmonary congestion, the heart may not appear to be enlarged; a striking inspiratory fall in arterial pressure may be present. However, there is also an inspiratory fall in venous pressure, thus differentiating the phenomenon from the true paradoxical pulse (p. 1468). If it is concluded that constrictive heart disease is present, the second problem is to determine the cause.

The basic abnormality in chronic constrictive pericarditis is the inability of the ventricles to relax adequately during diastole because of the limitations imposed by the rigid, thickened pericardium. This limits diastolic filling, and stroke volume is diminished; atrial, pulmonary, and systemic venous pressures are elevated to about the same levels, congestive hepatomegaly with ascites and occasionally congestive splenomegaly as well as peripheral edema appear. The heart sounds are distant, cardiac pulsations under fluoroscopic examination are diminished, an early diastolic gallop is heard, and a paradoxical pulse can be elicited. The course of the illness is slow and progressive, and the usual medical treatment is relatively ineffective and disappointing.

This description applies to the full-blown picture, but there are lesser degrees of disability, and one may encounter persons with thickened, calcified pericardium who lead normal unrestricted lives. The same physiologic abnormalities and the same clinical picture may be induced by other forms of constrictive heart disease. *Endocardial fibrosis, the various forms of endomyocarditis, extensive involvement of the myocardium by amyloid disease, scleroderma, fibrosis secondary to myocarditis, constrictive epicarditis (Porter's syndrome)* are all capable of inducing the same hemodynamic defect leading to a disorder that is practically indistinguishable from that caused by constrictive pericarditis. It has also been shown that diffuse and severe scarring of the myocardium caused by coronary sclerosis that has been responsible for no pain is another disorder that mimics constrictive pericarditis.

The lesson to be learned is that when a patient has progressive, disabling, and unresponsive congestive failure, and particularly if he displays any of the phenomena of constrictive heart disease, however minimal they may be, the only definite method of determining whether or not constrictive

hypoproteinemia, the contribution of heart failure to renal insufficiency can frequently be assessed only by the use of digitalis in a therapeutic trial. It is generally not necessary to reduce the daily maintenance dose of digitalis even in patients with severe renal excretory impairment. However, because of the vicious consequences of dehydration and salt depletion in such patients, casual administration of this drug to the point of toxic symptoms including nausea and vomiting should be avoided.

In many patients with renal insufficiency, *pulmonary edema* tends to be central, producing a "butterfly pattern" on the chest x-ray. Rales may be absent. Increasing agitation and restlessness, coupled with accentuation of the second pulmonic heart sound, are often the first warning to the physician of an impending explosion of paroxysmal dyspnea which may be warded off with digitalis. Diuretic drugs are generally ineffective when glomerular filtration rate is greatly restricted, i.e., when the blood urea nitrogen is over 80 to 100 mg per 100 ml. Chlorothiazide and its derivatives are probably safer under such circumstances than mercurials, which may, especially after repeated cumulative doses, cause necrosis of renal cells. Ammonium chloride and other acidifying diuretic agents are useless and may be harmful in renal insufficiency.

In every case of chronic renal insufficiency it is important to consider the possibility of lower urinary tract obstruction. Patients with chronic prostatic retention or urethral stricture, with overflow incontinence or infection that can be cleared only when the bladder is allowed to empty normally, may improve remarkably with drainage. Chronic partial obstruction to the flow of urine, either at the bladder outlet or at the level of the ureters (as in the syndrome of *perireteral fibrosis*), may produce azotemia without oliguria; in fact, urinary output may be increased because of the loss of concentrating power. In the bedridden and obtunded patient with chronic renal disease and advanced uremia, unrecognized functional difficulty in bladder emptying, often precipitated by sedatives, but treatable with Urecholine or Prostigmine, may be the cause of rapid and otherwise inexplicable deterioration. A delayed pattern of phenolsulfonphthalein excretion will sometimes supply the clue to the presence of bladder neck obstruction. An x-ray of the abdomen should be one of the initial studies of every patient with uremia, especially when oliguria is present, since calculi may obstruct both ureters simultaneously, or a single ureter when there is only one kidney. Failure to investigate the possibility of ureteral obstruction in such cases may be as disastrous as too vigorous instrumentation of the urinary tract in chronic nephritis.

A search for urinary infection should be made in

FIG. 257-1

every patient with chronic renal disease, and treatment with the appropriate antibiotic instituted if an infecting organism is found. In this connection, unnecessary instrumentation of the urinary tract should be avoided. In particular, the use of indwelling catheters should be strongly condemned except when absolutely necessary to relieve obstruction. Patients with indwelling catheters almost invariably develop an active urinary infection, even when receiving antibiotics prophylactically. The resulting necrotizing cystitis, active pyelonephritis, or bacteremia not infrequently proves fatal to the fragile patient with renal insufficiency.

Streptomycin, normally excreted by the kidney, may rapidly accumulate to toxic levels when given in usual doses to patients with impaired renal function. Tetracyclines also are excreted slowly in patients with damaged kidneys. Chloromycetin is inactivated normally, but its metabolic products are only slowly eliminated.

In azotemic patients without edema, congestive failure, or oliguria, restriction of salt is unwise as well as unnecessary. The intake of sodium by such patients should be encouraged, preferably as salty

FIG. 257-2

lying causes. Tumors of the bladder and the treatment of stones are considered in this second chapter. The mechanisms underlying stone formation and the problems of renal and bladder infections have already been discussed in Chaps. 20 and 50, respectively.

257 GENERAL ASPECTS OF RENAL DISORDERS

Franklin H. Epstein

The Relationship between Diseases of the Kidney and Hypertension. The association of cardiac hypertrophy with contracted kidneys and albuminous urine was commented on by Richard Bright; since that time the relationship between hypertension and renal disorders has been a fruitful subject for study and speculation. It is clear that renal distortion or scarring resulting from many diseases may cause arterial hypertension and generalized vascular disease (Chap. 245). Often, however, there appears to be only the most casual relationship between the degree of encroachment upon renal excretory function and the incidence or degree of high blood pressure. For example, hypertension may be severe and rapidly progressive in a patient with unilateral constriction of a renal artery, who has a normal urea clearance and phenolsulfonphthalein excretion (and even a normal "routine urine"). On the other hand, another patient with severe chronic pyelonephritis, marked azotemia, and anemia may have a normal blood pressure throughout most of his life, only to develop a mild elevation terminally. In a third patient, small areas of scarring caused by bilateral interstitial pyelonephritis, which are themselves insufficient to produce detectable impairment of renal function, may be associated with malignant hypertension. In turn, the generalized vascular disease which accompanies hypertension may involve renal parenchyma, thus creating and reinforcing a vicious circle.

Characteristic of the natural history of many renal disorders is a *latent period* between the initial insult to the kidney and the appearance of fixed hypertension. Thus, although polycystic kidneys are undoubtedly abnormal from birth, hypertension usually does not appear until the third or fourth decade of life. Following acute glomerulonephritis, blood pressure usually returns to normal, though other signs of activity may persist. If healing is incomplete, the patient may again become hypertensive years later, this time, perhaps, with the development of progressive azotemia. A similar latent period before the appearance of hypertension may mark the course of some patients who have suffered episodes of pyelonephritis or preeclampsia.

The Relationship between Signs of Renal Failure and Functioning Renal Mass. As illustrated in Fig. 257-1, the relationship between the plasma level of urea or creatinine and the rate of glomerular filtration takes the form of a hyperbola. The shape of this curve has important implications for the clinician, for it illustrates the extent of the physiologic reserve of the kidneys. Although the concentration of urea in the blood varies inversely with the glomerular filtration rate from the very first reduction in the latter, one-half to three-quarters of both kidneys can be removed before the level of non-protein nitrogen is necessarily elevated above "normal" limits. Conversely, if the blood urea nitrogen is persistently elevated in a patient with what appears at first glance to be only unilateral renal disease, impaired function of the opposite kidney must be suspected.

It is possible, very roughly, to generalize the relationship between functioning renal tissue and the signs and symptoms of renal failure in the same fashion, as in Fig. 257-2. The hyperbolic curve clarifies some aspects of the course of many chronic progressive renal diseases characterized by a long "latent" period and rapid terminal progression. One can visualize a slowly progressive process, relentlessly destroying renal substance, which is relatively asymptomatic for many years. When the limits of renal reserve are reached, symptoms appear in swift succession and the condition of the patient deteriorates rapidly, though there may be little actual acceleration of the rate of pathologic destruction of the kidneys.

The admittedly oversimplified curve of Fig. 257-2 provides a rationale for the treatment of patients with renal disease. The less kidney tissue there is remaining, the more difference an increment in function makes to the patient. The fragility of patients with little remaining renal function is apparent. Prolonged dehydration, the depressant effects of anesthesia, the circulatory shock of septicemia may be easily withstood by a person with normal or slightly impaired renal reserve but disastrous to a patient balanced on the knife-edge of renal decompensation. In evaluating the prognosis of a patient with renal insufficiency, the extent of damage that is *reversible* is obviously tremendously important. The goal of the physician in the treatment of advanced renal disease is the discovery and treatment of reversible disorders, no matter how insignificant they may at first appear, because for a patient on the steeply ascending portion of the curve, a small improvement in function may mean the difference between life and death.

Treatment of Chronic Renal Disease. One of the more important reversible disorders frequently contributing to uremia is *congestive heart failure*. In the presence of intrinsic renal disease, anemia, and

hemoglobin is below 8 Gm per 100 ml. Strenuous efforts to maintain normal or near-normal hemoglobin levels by transfusion are, however, useless and unnecessary. Unless serum proteins are depleted, or hemostatic defects are present, in which case whole blood should be given, transfusions should ideally be of packed red cells derived from fresh blood. Transfusion should be given cautiously in the presence of congestive heart failure, but treatment of severe anemia should not be neglected because the heart is failing; in such circumstances, transfusions should be of packed red cells given slowly in small amounts, with the patient in a sitting position. If blood is given at intervals to ambulatory patients with advanced renal disease before the red blood cell count has fallen to a critical level, general well-being and strength may be greatly improved and the remaining days made happier and more useful.

When *oliguria* is present, at any stage of renal disease, it is clear that the dietary intake of protein should be restricted, if not eliminated. Similarly, there is general agreement that protein intake should be increased in the nephrotic syndrome. Controversy still surrounds the proper prescription of protein in the diet of the large number of patients with chronic renal disease and azotemia who have an undiminished or increased urinary output. Unfortunately, adequate studies on the long-range effect of variations in protein intake on the course of renal disease in man are almost nonexistent. It would seem reasonable that the common sense of the physician and a consideration of the nutritional needs of the whole patient should control advice about diet. Chronic nephritis is a wasting disease. Patients are frequently protein-depleted and anemic. Fatigue, anorexia, and weakness are prominent complaints. In many cases malnutrition has been intensified by unreasonable fear of protein. Too often in renal insufficiency the patient's appetite forcibly limits any theoretical discussions of the optimum diet, but when a diet adequate in calories and protein can be supplied, a positive nitrogen balance (implying previous depletion of tissue stores of protein) can almost always be demonstrated. Obesity, to be sure, should be avoided, but where appetite is present, the clinician should be grateful and allow it full scope. A hungry patient, permitted to eat a diet normal in protein (1 Gm per kg per day), may exhibit a gratifying return of strength, appetite, and well-being. The commonly encountered belief that red meat and eggs are more harmful to patients with nephritis than the protein of fish, milk, or vegetables is not valid. Alcoholic beverages, in modest amounts, are not harmful to the kidneys, and their sedative qualities should not be neglected.

The neuromuscular disturbances of uremia are

often distressing and difficult to treat. Frank hypocalcemic tetany can be relieved by intravenous calcium salts (1 Gm calcium daily as the gluconate or chloride for 2 to 3 days), but the gross tremors, twitchings, and jactitations of uremia are generally not improved by the administration of calcium. Occasionally they disappear or improve when hyponatremia is corrected. Care must be taken not to mistake the rigidity, tremor, and occasional convulsive episodes which sometimes follow overdoses of the phenothiazine drugs for the neuromuscular deterioration of renal insufficiency. Convulsions are best controlled by the intravenous or intramuscular administration of sodium phenobarbital. Chloral hydrate (1 to 2 Gm nightly) and Benadryl (100 mg) are useful sedatives. Itching is an extremely variable symptom of uremia and not closely correlated with the level of blood urea. It may sometimes be controlled by daily cleansing baths, bland lubricating ointments, and the use of Benadryl or similar antihistaminic and sedative drugs. The author has occasionally observed relief when topical adrenal cortical steroids were used.

Vigorous treatment of hypertension with ganglionic blocking agents is often unsuccessful and may be hazardous when blood urea nitrogen reaches 60 mg per 100 ml or more. Under these circumstances small reductions in perfusion pressure and blood flow through the kidneys may precipitate renal decompensation. Cautious use of small doses of ganglionic blocking agents may be attempted when retinopathy or hypertensive heart failure is producing symptoms. Reserpine may be prescribed more freely, but is rarely completely effective. Sodium depletion with diet or diuretic agents generally is harmful to renal function. Hypertensive headaches may be treated with aspirin or phenacetin; when they occur on awakening, elevating the head of the bed often provides some measure of relief. In this phase of management, as in many others, *primum non nocere* should be the rule; the patient with chronic renal insufficiency and hypertension who is asymptomatic should in general be left alone.

The role of artificial dialysis in the management of chronic renal disease has not been well delineated. It seems clear that some patients with chronic renal insufficiency, especially those in whom vascular disease is not far advanced, can be helped through an otherwise fatal complication, such as an acute infection or a surgical operation, by the judicious use of dialysis. Patients with chronic glomerulonephritis in whom an attempt has been made to prolong life by repeated hemodialysis have eventually succumbed to rapidly progressive vascular complications or infection. Transplantation of a normal kidney from an identical twin has been successfully accomplished in a few patients with chronic

foods and drinks, rather than pills of sodium chloride, which tend to irritate the stomach. The slight expansion of extracellular fluid induced by a diet high in sodium is often reflected in improved renal blood flow and glomerular filtration. Excretion of urea, sulfates, and phosphates is augmented, and the secretion of acid and potassium is promoted (Chap. 51). Because salt stimulates thirst, the intake of water is encouraged in a natural fashion and urinary flow is improved. The appearance of congestive failure sharply limits the extent to which an increased intake of salt can be used as a lever to improve renal function in chronic renal disease. Because of the beneficial effects of salt on renal function, an attempt should be made to control early congestive heart failure in patients with chronic renal disease with digitalis, rather than by rigid limitation of dietary sodium. Unnecessary restriction of salt and consequent salt depletion may, in fact, result in considerable further impairment of renal function in many patients with renal insufficiency who are unable to conserve sodium in the normal fashion when the intake of this ion is limited (p. 172). Salt-wasting is more common in patients with chronic pyelonephritis than chronic glomerulonephritis but may occur in renal insufficiency of any etiology, in such cases the triad of asthenia, dehydration, and hyponatremia may even suggest the diagnosis of Addison's disease. From 5 to 8 Gm sodium chloride daily may be required to prevent sodium depletion. Salt-losing may disappear or become less marked in the terminal stages of renal failure, as glomerular filtration becomes progressively compromised, congestive heart failure makes its appearance, and oliguria supervenes.

The systemic acidosis which accompanies chronic renal insufficiency is often responsible for mild to severe nausea, fatigue, malaise, and breathlessness on exertion, long before Kussmaul respirations are clinically apparent. Prescription of the equivalent of 4 to 6 Gm sodium bicarbonate daily (as, for example, 1 to 2 tsp of 10 per cent sodium citrate in syrup of wild cherry, after each meal) usually suffices to maintain serum bicarbonate at 18 to 22 mEq per liter, and thereby to avoid the unpleasant side effects of acidosis. Excessive administration of alkali must be avoided, especially in the presence of hypocalcemia (p. 470), where correction of acidosis without the simultaneous administration of calcium may precipitate tetany or convulsions. Large amounts of sodium bicarbonate or lactate are also contraindicated in congestive heart failure.

Because of the obligatory polyuria evident in most patients with chronic renal insufficiency, dehydration may be readily produced, even by relatively brief abstinence from fluids. Thirsting and purgation in preparation for x-ray studies may prove fatal in the delicately balanced patient with renal decom-

pensation. In such patients it is usually unnecessary and unwise to withhold fluids before blood is drawn for chemical determinations in the morning. Even minor surgical procedures should be undertaken against a background of adequate hydration, by the intravenous route if necessary, both before and after operation. Overnight polyuria in many patients results in early morning thirst and a feeling of hunger on awakening which quickly turns to nausea and vomiting, thereby perpetuating the vicious circle of dehydration. This can sometimes be prevented by taking a drink of water after urinating at night or be allayed by a small preliminary feeding immediately after waking.

The treatment of nausea in patients with chronic renal disease should, as already indicated, include close attention to proper hydration, correction of acidosis, and treatment of sodium depletion. Anorexia is one of the first signs of a low serum sodium, and nausea is often dramatically improved when hyponatremia is corrected. The administration of one of the phenothiazine derivatives several times daily or of Benadryl, coupled with small frequent feedings, has proved helpful. The pattern of meals should be adjusted flexibly to take advantage of the patient's sometimes unpredictable periods of hunger and well-being. When vomiting is persistent, all feeding should be stopped and fluids given intravenously for 1 or 2 days. The vomiting which marks the terminal stage of nephritis may be particularly intractable; it is one of the few types that will continue after all food and fluids are withheld. Although restriction of the fluid intake is contraindicated, there is no reason to push fluids to the point of discomfort. The efficiency of the kidney in excreting urea and other solutes appears to reach a maximum at a urine volume of 2,500 to 3,000 ml; even the diseased kidney is not much more effective at higher volumes. Moreover, the ability to excrete large loads of water rapidly is impaired in most patients with azotemia. Excessive administration of water, especially when salt intake is limited, is likely, therefore, to result in hyponatremia, with its attendant symptoms of nausea, muscle cramps, and mental disturbances.

The anemia of renal insufficiency is unresponsive to liver and to iron. The latter may be given in a therapeutic trial, but if it is effective, it may reasonably be concluded that the anemia is not the product of uncomplicated renal failure. Reticulocytosis is reported to follow the administration of cobalt, but gastric irritation generally precludes the use of this medication in effective doses. For the treatment of the anemia of advanced renal disease, reliance must be placed on transfusions. Although the degree of tolerance to anemia varies greatly, weakness, shortness of breath, and poor appetite are likely to be improved by transfusions when the

258 DISEASES OF THE KIDNEYS

Franklin H. Epstein

ACUTE GLOMERULONEPHRITIS

Acute glomerulonephritis is an acute, diffuse inflammation of the glomeruli of the kidneys. It represents about 0.5 per cent of all admissions to general hospitals in the United States and is found at autopsy in 0.1 to 0.2 per cent of deaths. The disease is twice as frequent in males as in females. Although it is commoner in children than adults, it may occur in adults of every age.

Etiology. Acute glomerulonephritis is best thought of as a pattern of reaction of the kidneys, rather than as a single disease with a specific etiology. Preceding infection with the group A, β -hemolytic streptococcus is by far the most common cause (p. 918). The infection usually arises in the upper respiratory tract, and its severity is not necessarily related to the incidence or severity of the ensuing nephritis. Streptococcal infection of the skin or of wounds may also be followed by glomerulonephritis. There is considerable evidence that only certain strains of group A streptococci are nephritogenic; these include types 12, 4, 25, and Red Lake.

Acute nephritis has been reported by Bates, Jennings, and Earle as a complication of an epidemic of acute pharyngitis, presumably of viral origin, in which streptococcal infection was excluded by bacteriologic and immunologic evidence. Bacterial endocarditis is frequently complicated by acute glomerulonephritis. Glomerulonephritis has occasionally been reported to follow other acute infections, but most such reports lack convincing evidence to rule out associated streptococcal infection.

Acute hemorrhagic nephritis superficially resembling the poststreptococcal variety may occur in the course of lupus erythematosus, periarthritis, or erythema nodosum. It is commonly seen as a complication of the allergic purpuras, associated with joint or abdominal pain. Finally, it may be a manifestation of hypersensitivity to drugs or other foreign agents.

Pathogenesis. Attempts to produce acute glomerulonephritis in animals by establishing an infection with streptococcus or by injecting dead or living streptococci have generally been unsuccessful. Nevertheless, it seems possible that alteration of glomerular tissue, perhaps by a blood-borne product of the streptococcus, is the first step in the pathogenesis of most cases of acute nephritis in man. The disease is probably the result of an autoimmune reaction, in which components of the glomeruli and perhaps of small blood vessels in the kidney, injured or modified by an inciting agent,

serve as antigens. The evidence for this can be summarized as follows. (1) There is invariably a latent period (which may last 1 to 4 weeks but averages 10 to 14 days) between the acute streptococcal pharyngitis and the first manifestations of acute nephritis. (2) Serum complement falls coincident with the attack of acute nephritis (presumably as a result of combination with antigen and antibody in the kidney). (3) High concentrations of gamma globulin can be detected on the basement membrane of injured glomeruli in renal biopsies from patients with acute glomerulonephritis. It is of interest in this connection that heterologous immune responses are much more easily demonstrated with components of glomerular basement membrane than with glomerular epithelial and endothelial cells and that the globulin fraction of antikidney serums prepared in animals can be shown to attach primarily to glomeruli.

Although the clinical picture as seen in man has not been exactly reproduced in animals, the most convincing experimental analogues of glomerulonephritis are those produced by injecting specific antibodies to the kidney (Masugi nephritis). Whole kidney tissue or glomeruli from one animal are injected into another species, antibodies are allowed to develop, and after an appropriate interval, serum from the second animal is injected intravenously into a new member of the original species. Proteinuria, hypertension, and nitrogen retention occur. The onset of the nephritis is generally abrupt but is sometimes (like poststreptococcal nephritis) characterized by a latent period. The lesions of the disease may heal, or they may become chronic. It is of some interest to students of the toxemias of pregnancy that antibodies to placental tissue are also nephrotic.

Lesions resembling glomerulonephritis are also observed in rabbits as part of the generalized anaphylactic reaction involving vascular endothelium which follows sensitization to foreign proteins. These have an obvious analogy to those cases of nephritis in human beings associated with hypersensitivity reaction.

Pathology. The kidneys may be normal in size, but as a rule are swollen. The surfaces are usually smooth and spotted with fine punctate hemorrhages; the pyramids are markedly congested. The histologic picture may vary considerably, probably as a result of differences in the duration of the process and the degree of immunologic reaction as well as in the nature and intensity of the provocative agent. All or almost all glomeruli are generally involved; yet the degree of inflammation may vary from one to another and be focal in distribution inside the glomerular tuft. In poststreptococcal nephritis, the glomeruli are usually swollen and hypercellular, with thickened glomerular loops, infiltrating poly-

renal disease, with disappearance of the uremic syndrome. Immunologic barriers, however, continue to prevent the successful transplantation of organs from nonidentical donors.

Approach to the Diagnosis of Asymptomatic Proteinuria. A few points in the study of the patient with asymptomatic proteinuria deserve special emphasis. Postural proteinuria (p. 173) should be ruled out, as well as the proteinuria which is normally associated with exercise or which follows certain febrile diseases. A careful history should inquire into the possibility of recent respiratory or skin infections, recurrent pyelitis, edema or hypertension during pregnancy, arthritis, rash, and drug sensitivity. A history of enuresis past the age of six may suggest congenital structural or neurologic anomalies of the urinary tract or chronic childhood pyelitis. The results of prior examinations for employment, insurance, or military service should be ascertained. The family history may be positive for renal and vascular diseases; inquiry should also be made about gout and diabetes. Blood pressure should be checked in the erect as well as supine position and retinal as well as peripheral vessels examined. Amyloidosis may be suggested by an enlarged liver or spleen; the presence of palpable masses in both upper quadrants should also raise the question of polycystic kidneys. Physical examination should not overlook the possibility of a cystocele or enlarged prostate.

A clean urine should be obtained and cultured (p. 1037). Examination of a *fresh* urine sediment by the physician is a most important diagnostic maneuver. The composition of casts is particularly significant. Clumps of leukocytes and white blood cell casts with or without bacteria apparent on the stained smear suggest pyelonephritis. Leukocyte casts are also sometimes seen in acute glomerulonephritis. If hematuria is accompanied by red blood cell casts, an active hemorrhagic lesion in the glomerulus is likely. Red blood cells and epithelial cells entrapped in casts, together with casts containing lipid droplets, should suggest glomerulonephritis, without distinguishing among its various etiologies. It should be emphasized that the absence of characteristic formed elements in the urinary sediment does not rule out either chronic glomerulonephritis or pyelonephritis. If more than 2 to 3 Gm of protein is excreted in the urine daily, a generalized disease primarily affecting glomeruli is likely to be present. Congestive heart failure and malignant hypertension, regardless of etiology, may also be associated with heavy proteinuria.

Blood urea, serum creatinine, and phenolsulfonphthalein excretion are useful in assessing the degree to which renal reserve has been impaired. If the blood urea nitrogen is over 20 mg per 100 ml or the serum creatinine above 2.0 mg per 100 ml, it

is likely that both kidneys are involved by the disease process. A phenolsulfonphthalein excretion of less than 25 per cent in 15 min or 60 per cent in 2 hr is indicative of renal impairment; excretion which is greater during the second hour than the first may suggest hydronephrosis or incomplete bladder emptying. (Inadequate urine volumes in the 15-min sample may be avoided by starting the phenolsulfonphthalein test after the patient has been hydrated and injecting the dye only after he feels an urge to void.) Occasionally, a disproportionate elevation of blood uric acid will suggest underlying gouty nephropathy. Examination of the blood for LE cells or of the serum for antinuclear antibodies may detect early lupus erythematosus. Electrophoresis of the serum may reveal globulins characteristic of multiple myeloma.

The size and shape of the kidneys as well as the structure of calyces and ureters may be ascertained from an intravenous pyelogram. At the conclusion of this examination, a postvoiding film of the bladder may give information about residual urine without the necessity for catheterization. The size of the kidneys can be estimated in relation to the vertebral shadows on the plain film of the abdomen, normal kidneys are approximately as long as three to three and one-half lumbar vertebral bodies. When one kidney is shrunken and the other has failed to hypertrophy, disease is usually bilateral.

Percutaneous needle biopsy of the kidney has provided much useful information for the student of renal disease, but even in the most skillful hands, it is not without hazard. In the author's experience, it has not infrequently contributed helpfully to the management of the individual patient (e.g., the unexpected finding of amyloidosis or periarthritis; the detection of advanced changes of pyelonephritis in an apparently uninvolved kidney), but its greatest value has been to illuminate the still ill-defined natural history of diffuse diseases of the kidney. The accuracy of needle biopsy as a diagnostic technique is limited in focal disorders of the kidneys by the small size of the specimen and in diffuse glomerular disease by the fact that the sample obtained may contain no or few glomeruli. In most patients with proteinuria, proper use of the more conventional diagnostic methods will permit an accurate working diagnosis. Interpretation of biopsy sections must be made with proper regard to the rest of the clinical and laboratory findings and to the fact that, in this relatively new area of clinical investigation, both pathologist and clinician still have a great deal to learn.

Finally, the diagnostic maneuver of *following the patient*, in addition to being innocuous, has a great deal to recommend it. Acute or self-limited processes, even when the histologic picture is clear, can sometimes be diagnosed only in retrospect.

failure responsive to digitalis (and associated with a prolonged circulation time) may at times complicate acute nephritis. When orthopnea is present, especially if accompanied by rales or gallop rhythm, digitalis should be prescribed. In other instances of edema and elevated venous pressure, a careful therapeutic trial of digitalis should be undertaken, with the knowledge that in many instances it will be found ineffective.

Hypertension is observed in approximately 50 per cent of adults with nephritis admitted to a general hospital. The incidence may be lower in mild cases detected in the course of a streptococcal epidemic. The onset is usually coincident with the first abnormal urinary findings, although in certain cases it may even precede and in others follow them. The elevated blood pressure is presumably caused by the release of renin, which has been detected in the peripheral blood of patients with fulminating acute nephritis.

The optic fundi are generally normal but may show arteriolar narrowing and in exceptional circumstances, papilledema, hemorrhages, and fluffy exudates.

When the blood pressure rises rapidly, headache, somnolence, and convulsions may develop, simulating in an occasional case the clinical picture of brain tumor. The differential diagnosis in such instances is not made easier by the fact that proteinuria and microscopic hematuria are often detected immediately following generalized seizures of any origin. Vomiting, dehydration, and heart failure appear to predispose to convulsions. They are not dependent on nitrogen retention but are probably the result of cerebral ischemia or tiny hemorrhages secondary to changes in the cerebral vasculature.

Mild anemia occurs frequently in acute glomerulonephritis, especially with edema. Total red cell volume has been found to be normal in many such patients, in whom the low hematocrit reflects dilution. In addition, depression of the bone marrow and increased destruction of red cells may contribute to anemia in certain azotemic patients. Serum albumin may be low, as a result of urinary losses and of the excessive catabolism of protein observed in many acute diseases or injuries. Serum cholesterol may be elevated, even when serum albumin is not greatly decreased. The presence of anemia and hypercholesterolemia, then, does not necessarily mean that nephritis is chronic or progressive.

Changes in renal function which occur in acute nephritis are characteristic. Glomerular filtration rate is usually depressed, and to a greater degree than renal blood flow. The latter may, indeed, be elevated, though in severe cases it falls as well. Filtration fraction is therefore reduced. Blood urea nitrogen is elevated in perhaps half of the patients

with glomerulonephritis. In cases of mild or moderate severity, phenolsulfonphthalein excretion is either normal or only slightly decreased, even when the blood urea nitrogen is elevated. With more severe initial involvement, or with progression of the disease, excretion of phenolsulfonphthalein may fall. Acid urine of high specific gravity may be excreted early in the course of the illness, despite pronounced azotemia. The combination of azotemia with well-maintained phenolsulfonphthalein excretion and high urinary specific gravity is seen in few diseases of the kidney other than acute glomerulonephritis.

The urine may be grossly bloody or coffee-colored; on the other hand hematuria may be apparent only on careful inspection of the spun sediment. The identification of red cells embedded in casts establishes the glomerular origin of the bleeding. Granular and epithelial cell casts, especially the latter, are characteristically present. Lipid droplets and fatty casts are usually not present at the very onset of the disease, but may appear within the first few weeks, regardless of the presence or absence of hyperlipemia in the serum. Leukocytes and white blood cell casts reflect the essentially inflammatory character of the glomerular lesion. Proteinuria may reach impressive levels, over 6 to 8 Gm daily, but is more often below 2 Gm per day. Especially during recovery, protein may disappear from the urine while red cells and red cell casts continue to be excreted.

The disease is sometimes ushered in by a period of oliguria which may progress to complete anuria. Usually this lasts only a few days, but an occasional case of anuria lasting more than 10 days has been reported in acute glomerulonephritis followed by complete recovery. The oliguria which occurs at the onset of acute nephritis has a much better prognosis than that which may supervene when the disease has been active for several weeks. In contrast to patients with acute tubular necrosis, urinary sodium concentration is very low (less than 15 mEq per liter) in oliguria secondary to glomerulonephritis, and urinary osmolality is often significantly above that of plasma.

Extrarenal vasculitis may be an important concomitant of acute nephritis. Its myocardial and cerebral manifestations have already been mentioned. Purpuric rashes, subungual hemorrhages, and even acute arthritis may rarely be seen in the course of severe poststreptococcal nephritis. At postmortem, necrotizing and organizing lesions of periarteritis may be found in the kidneys and elsewhere.

Finally, it should be emphasized that patients may develop acute nephritis with no symptoms and no abnormal physical or laboratory findings other than mild proteinuria and an abnormal urinary sediment.

morphonuclear leukocytes, and proliferation of endothelial and epithelial cells. Occasionally, however, especially when function is completely recovered, but while the urine sediment is still abnormal, renal biopsy will reveal glomeruli which appear normal except for occasional focal thickening of basement membranes. Red cells and red cell casts are present in the tubular lumens. Tubular cells may appear flattened or vacuolated, but pathologic changes in tubules are minimal compared with those in the glomeruli. Afferent arterioles may sometimes show focal medial necrosis with perivascular cellular infiltrates, and there may be similar lesions of the interlobular vessels.

As the disease process subsides, there may be resolution of the inflammatory process, with restoration of normal architecture. More frequently, hyalinized glomeruli, glomerular adhesions, and vascular changes persist, with wedge-shaped areas of atrophy and fibrosis separated by areas of relatively well-preserved tissue in which the remaining tubules are dilated. Even after the urine has completely cleared, focal hypercellularity and thickening of the stalks of glomerular lobules may persist. Widespread proliferation of the capsular epithelium, producing glomerular "crescents," is a characteristic finding in those patients who deteriorate rapidly, dying with hypertension and oliguria within 1 to 12 months of the onset of the disease.

Clinical Features and Pathologic Physiology. Common clinical manifestations of poststreptococcal glomerulonephritis are detailed on p 918. The clinical picture is not infrequently dominated by one or more signs or symptoms which overshadow the rest and may initially mislead the physician who anticipates a "classical" pattern. Frequent presenting symptoms include anorexia, abdominal pain, facial edema, congestive heart failure, gross hematuria or coffee-colored urine, oliguria or anuria, and unexpected convulsions.

Fatigue and anorexia are almost universal; it is unusual for a patient with acute glomerulonephritis to feel as well as before the illness or to have a good appetite.

Pain in the loins or abdomen may be colicky or steady, and in exceptional instances, so severe as to simulate a surgical condition. Fever generally does not exceed 101°F and usually subsides within a few days after hospitalization; persistent fever may sometimes be caused by residual streptococcal or other infection or by a reaction to antibiotics.

Although facial edema is extremely common, edema of the legs without any swelling of the face is frequent, especially in older persons. Edema may be generally distributed and hence unapparent, and the only clue to its presence may be a 5- or 8-lb weight loss after the patient is put to bed and given a low-salt diet. Localization of edema about

the eyes is best explained by the low tissue turgor in this region. The absence of orthopnea, at least during the early stages of the disease, further favors accumulation of fluid in the upper half of the body during the hours of sleep.

Whether salt and water retention in acute nephritis is primarily due to renal disease per se or secondary to other circulatory disturbances which provoke even normal kidneys to retain sodium is not entirely clear. Considerable evidence suggests that disproportionate reduction in glomerular filtration rate is responsible for the initial oliguria and subsequent retention of sodium which result in excessive accumulation of extracellular fluid. Edema formation is generally associated with some decrease in the inulin clearance, and diuresis with a fall in blood urea nitrogen. Nevertheless, diuresis may be initiated in acute nephritis without any measurable improvement in a depressed filtration rate; the relationship between impaired inulin clearance and sodium retention is therefore not simple or clear-cut.

Generalized capillary damage is probably not a cause of edema in nephritis, since the edema fluid does not contain increased amounts of protein. Although hypoalbuminemia resulting from extensive losses of plasma protein into the urine may contribute to edema in some cases, this factor cannot be the most important one in the many instances where plasma volume, by direct measurement, is increased or normal. Urinary excretion of aldosterone may be low in acute glomerulonephritis in the presence of edema, even when the patient is on a salt-free diet. As might be expected in such a situation, spironolactone does not provoke diuresis. Renal retention of sodium under these circumstances is probably a result of altered renal hemodynamics, rather than excessive secretion of salt-retaining hormone by the adrenal cortex.

Together with edema, signs and symptoms of congestive heart failure are often prominent, whether or not arterial hypertension is present. The sudden onset of heart failure in a previously well person may be the manifestation which brings the patient with acute nephritis to the doctor. Fatal pulmonary edema may be precipitated by convulsions. The heart is usually somewhat enlarged, and the venous pressure may be elevated. Nonspecific alterations in the electrocardiogram are common. Unlike the pattern of "low-output" cardiac failure, the circulation time is typically normal or short, and cardiac output is normal even when edema is present or increasing. Under such circumstances cardiac output does not rise further when digitalis is administered. It seems probable that, in most cases, circulatory congestion is a result of fluid retention rather than its cause.

It should be emphasized, however, that heart

which predominantly affect the glomerular tufts, causing inflammatory changes and subsequent scarring. The course and pathologic findings vary widely, not only because of diverse etiologies, but also because of variations in the response of different patients to the same injurious agent. It may be expected that, as knowledge of the nature of renal disease expands, additional nosologic entities will emerge from the group termed "chronic glomerulonephritis" as distinctly as Kimmelstiel-Wilson disease and lupus nephritis have in the past.

Chronic glomerulonephritis affects all ages, but is most frequent in the earlier periods of life. It is more common in men than in women. Only a minority of patients have a clear-cut history of acute onset following infection or have evidence of antibodies against nephritogenic strains of streptococci. Some cases of chronic nephritis probably originate in an unapparent infection with streptococcus, following which edema or bloody urine was not noticed, but it seems likely that many instances represent a different disease from that of poststreptococcal glomerulonephritis. Occasionally a strong familial predisposition to chronic nephritis is apparent. Some characteristic patterns are considered below.

"Crescentic Glomerulonephritis." The entire course lasts only a few months, usually less than a year. Sometimes the onset is explosive, originating in acute nephritis following an infection. In other instances evidence for an infectious etiology is absent and the beginning of the disease can be dated only by the last normal examination. In any case, fatigue, anemia, and breathlessness quickly appear, hypertension is prominent even though the heart may initially not be enlarged, the urine contains large quantities of protein and red cells and may be grossly bloody. Oliguria and rapidly advancing uremia, complicated by pulmonary edema, characterize the terminal weeks. The kidneys are usually normal in size, and the glomeruli are swollen, with intense proliferation of the capsular epithelium, resulting in widespread crescent formation.

"Latent Nephritis." Abnormal urinary findings may be detected in a completely asymptomatic patient in the course of a routine physical examination. Renal biopsy may show a patchy glomerulitis, with focal thickening of glomerular loops, occasional capsular adhesions, and some completely hyalinized glomeruli. Other glomeruli may appear completely normal. Alterations in arterioles of the kidney can sometimes be detected even though blood pressure is normal.

Hypertension is often absent. The fundi are normal. The usual tests of renal function may be completely within normal limits, and serial studies over many years may show no or very slow progression of functional impairment. The character of the uri-

nary sediment is often a poor guide to prognosis; moderate proteinuria, red cells, and red cell casts may be present intermittently or continuously for years, with a normal or only slightly elevated serum creatinine. There is reason to believe that the pathologic process is continuously active at a low level, though counterbalanced by forces of repair and renal hypertrophy. Some patients live normal lives for decades without any change, or occasionally are cured; others eventually develop severely impaired renal function and hypertension.

Pregnancy may in some cases be safely undertaken by patients in whom hypertension has not appeared and whose blood urea nitrogen is normal; in others the risk of pre-eclampsia or exacerbation of nephritis is greatly increased.

Nephrotic Syndrome. In the course of glomerulonephritis in some patients the disease begins insidiously with nightly swelling of the ankles and early morning puffiness of the eyes. Proteinuria is in excess of 5 Gm daily, and serum albumin is low. Hypertension may or may not be present initially but eventually makes its appearance. Renal biopsy may reveal diffuse thickening of all glomerular loops, with little or no cellular proliferation, capsular adhesions, or crescent formation, though all these changes may be present in occasional instances. In some cases interlobular thickening in the glomerular tufts is focal rather than diffuse (chronic interlobular glomerulonephritis), resulting in a pathologic picture that superficially resembles the nodular form of Kimmelstiel-Wilson disease. The rate of progression of the lesion is extremely variable, though within 6 years perhaps half of all patients will have developed the uremic syndrome. Occasional patients appear to recover completely. In many cases, edema remits as the glomerular filtering area is progressively restricted and the excretion of protein falls, in others, hypoalbuminemia and edema persist to the end.

Hypertension. Many patients with chronic glomerulonephritis seek medical attention because of complaints associated with hypertension. Sometimes high blood pressure will be found to have developed without significant impairment of renal function. Such cases may be indistinguishable in their clinical manifestations and course from benign essential hypertension, except for the fact that proteinuria, dating in occasional instances from a clear-cut attack of acute nephritis, has antedated the hypertension. In some instances "malignant hypertension," with papilledema and extremely high diastolic blood pressure, may develop and dominate the picture. In patients in whom azotemia has not become pronounced, judicious use of ganglionic blocking agents may produce a remission in the pattern of malignant hypertension without seriously damaging renal function.

Differential Diagnosis. Periorbital edema, occurring as an initial symptom of urticaria, trichinosis, infectious mononucleosis, or insect bites about the face, may suggest acute nephritis until the urine is examined. The finding of red cell casts and the coincidence of an elevated blood urea nitrogen with normal phenolsulfonphthalein excretion serve to exclude many other diseases of the urinary tract, in which glomeruli are not primarily affected. The nephritis associated with lupus, polyarteritis nodosa, and subacute bacterial endocarditis will often be recognized as a complication of the primary disease, but sometimes may be its only manifestation. The characteristic elevation and subsequent fall of antistreptolysin titer is excellent evidence of preceding streptococcal infection, but may not be present, especially when the infection has been treated with penicillin. Gross hematuria with lower urinary symptoms is much more likely to be due to hemorrhagic cystitis or prostatitis. In middle-aged and elderly men, azotemia and hematuria may be mistakenly ascribed to the prostate until the daily excretion of protein is found to be greater than 2 Gm, suggesting the correct diagnosis of glomerulonephritis. The presence of small kidneys or of severe anemia (less than 8 Gm of hemoglobin) suggests chronic renal disease, as do the stigmata of prolonged hypertension in heart, blood vessels, and fundi. The appearance of acute nephritis immediately following a respiratory infection, without a latent period, suggests an acute exacerbation of chronic nephritis. Persistent fever, cardiac murmurs, or a palpable spleen should spur a search for subacute bacterial endocarditis.

Course and Prognosis. The course and outlook of acute glomerulonephritis vary widely. In children or young adults who develop nephritis following streptococcal infection, the entire disease may be over within 2 to 4 weeks. Most patients recover completely, although a small number (less than 10 per cent) go rapidly downhill and die within the first few months. On the other hand, in the adult population of a general hospital, the likelihood of chronicity appears to be much greater. It has been estimated that 20 to 50 per cent of adult patients hospitalized with acute glomerulonephritis either succumb to the acute episode or go on to develop chronic disease. The latter may be quiescent for long periods and manifested only by proteinuria and an abnormal urinary sediment. The ultimate outcome bears a rough relation to the initial severity of the illness, though there are many exceptions to this rule. The most frequent duration of the disease in hospitalized adults is probably about 2 to 3 months. Blood pressure usually returns to normal before the urine clears. Heavy proteinuria lasting longer than 3 to 4 months suggests a poor prognosis, though nephritis may heal

completely even after proteinuria has been present for as long as 2 years. Microscopic hematuria commonly persists for some months after proteinuria has disappeared or diminished to a faint trace. Postural dizziness, easy flushing, and other signs of autonomic instability, as well as postural proteinuria, are not infrequent during convalescence. After the urine has become completely normal on several examinations, a second attack of nephritis is extremely unlikely, probably because of the persistence of type-specific antibodies to the hemolytic streptococcus.

Acute nephritis associated with anaphylactoid purpura (Henoch-Schönlein disease) has a much worse initial prognosis and higher incidence of chronicity than the poststreptococcal variety.

Treatment. Penicillin should be given to eradicate residual streptococcal infection, even when this is not proved, but only suspected. It has been suggested that early treatment of streptococcal infections with penicillin may prevent nephritis, but in the only study performed to test this hypothesis the number of patients observed was too small to draw statistically valid conclusions.

During the acute stages *bed rest* is indicated, at least until the systemic manifestations of the disease have disappeared. There is no critical evidence to establish that further rest in bed appreciably modifies the course, although most studies concerned with this problem have been carried out in cases of mild nephritis in children in whom complete recovery is the rule. If proteinuria or microscopic hematuria is the only remaining sign after 6 weeks to 2 months of rest in bed, the patient may be allowed up.

In the presence of *edema*, salt should be restricted. Mercurial diuretics are contraindicated. Chlorothiazide may be employed. Treatment for congestive heart failure is discussed above and on p. 1385. During the initial stages of the disease, when urinary output is restricted, it may be wise to limit the intake of protein as outlined below under Acute Renal Failure (Treatment). There is no reason, however, to restrict protein during convalescence.

Hypertensive crises may be treated with 25 mg of reserpine intramuscularly two to four times a day or by an infusion of magnesium sulfate.

Adrenal steroids have no clear-cut beneficial effect in acute nephritis. When massive doses of steroids and of nitrogen mustards have been used in occasional instances of rapidly progressive glomerulonephritis with oliguria, they have failed to modify the course.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis is in all likelihood not a single entity but a collection of different diseases

except possibly in patients in whom frequent exacerbations are clearly related to respiratory infections. Prophylactic administration of penicillin (p. 921) may have similar theoretical advantages but has not been shown to alter the course of the disease. Treatment of the nephrotic syndrome is dealt with on p. 1490 and management of renal insufficiency on p. 1475.

CHRONIC PYELONEPHRITIS

Chronic pyelonephritis is present in 6 to 8 per cent of autopsied patients and accounts for over one-third of those dying with uremia. Up to middle age it is far more frequent in women, for the reasons mentioned on p. 1037. In old age, obstruction of the bladder in males by prostatic hypertrophy restores the balance. In contrast to the preponderance of women with pyelonephritis in the clinic, the incidence of pyelonephritis at postmortem is approximately equal in men and women. This may be a reflection of the frequency of lower urinary symptoms in women or of the nonspecific nature of some of the morphologic changes usually attributed to chronic or repeated bacterial infection.

About two-thirds of patients with chronic pyelonephritis have an obstructive lesion of the upper or lower urinary tract. In a large proportion of patients, however, there is no evidence of predisposing disease, obstructive or otherwise.

Pathology. The kidneys are frequently asymmetrical in size. The parenchyma is scarred, and the surface is coarsely and irregularly pitted. In many areas glomeruli and tubules are completely replaced by connective tissue which may contain lymphocytes and plasma cells. Foci of active interstitial inflammation may be seen throughout medulla and cortex, and leukocyte casts are found in some tubules. Other tubules are dilated and contain large amounts of homogeneous eosinophilic material (colloid casts). Most glomeruli appear relatively normal in comparison with the nearby atrophic tubular and inflammatory interstitial changes. The capsule of many glomeruli is disproportionately thickened and fibrotic in contrast to the relative integrity of the malpighian tufts. Some glomerular loops may be thickened or hyalinized, probably as a result of vascular changes proximally, and there are cortical clusters of fibrotic glomeruli, especially within the wedges of atrophic areas. Often distinctive inflammatory changes in the pelvic mucosa are lacking. A proliferative endarteritis is usually present, most marked in the areas of chronic inflammation. More generalized and severe vascular changes develop with the onset of hypertension.

It should be emphasized that, even at the autopsy table, the diagnosis of chronic pyelonephritis is often not clear cut. None of the foregoing changes

is pathognomonic of chronic infection of the kidneys, though when taken together, they are useful in suggesting the diagnosis. Similar morphologic features may be encountered as a result of other diseases, including the nephropathy of chronic potassium depletion, nephrocalcinosis, chronic phenacetin poisoning, and primary vascular disease of the kidneys.

Clinical Features. "Starting with a pyelitis in childhood, an infection of the urinary tract during pregnancy, or, in rare instances, an acute pyelonephritis, there may be from time to time attacks of unexplained fever, with or without slight or fairly severe pain in the lumbar regions. These attacks are often accompanied by the passage of cloudy urine. Occasionally there is a history of albuminuria of many years' duration. Often there is a story of malnutrition or sometimes of retarded growth in children, leading occasionally to rickety deformities. In some instances the progress of the disease is, for years, symptomless" (Longcope). The majority of patients fall into the last-named category. Early symptoms are particularly infrequent in the group with bilaterally atrophic, nonobstructed kidneys. A history of acute pyelitis in childhood may be especially difficult to obtain because the symptoms are mainly gastrointestinal, the physical signs are scanty, and pyuria is difficult to demonstrate; a history of persistent enuresis is sometimes the only helpful clue.

Patients often, therefore, come to the attention of the physician only when renal failure or hypertension has made its appearance, or because of the accidental discovery of proteinuria. Fatigue and lassitude associated with anemia may be the presenting complaints. If renal failure is severe, nausea and vomiting or breathlessness may be present. Edema is rare, and when it occurs it is a result of heart failure. Hypertension may be accompanied by headaches, visual disturbances, and signs of congestive failure. Splenomegaly occurs in some patients with chronic pyelonephritis; when it is associated with anemia, a primary hematologic disease may be simulated.

About two-thirds of patients with chronic pyelonephritis develop hypertension at some time in the course of their illness. It has been suggested that this is related to the contraction of scar tissue and to endarteritis obliterans with focal renal ischemia, rather than to diffuse renal damage. The blood pressure may become elevated long before there is measurable impairment of renal function, and only a persistently positive urine culture or characteristic changes in the intravenous pyelogram may distinguish the clinical picture from that of "essential" or "malignant" hypertension. The incidence of hypertension is greater in the interstitial, nonobstructive form of pyelonephritis than in the obstructive

Exacerbations of Chronic Nephritis. Respiratory infections, especially with the streptococcus, sometimes cause an increase in proteinuria, hematuria, and hypertension as well as a variable decrease in renal function in patients with chronic nephritis. These exacerbations may be distinguished from attacks of acute nephritis, which they resemble, by the short latent period between the onset of the infection and the exacerbation. In some patients, reversible exacerbations of vascular disease characterized by rising blood pressure, hematuria, and retinitis occur without evidence of preceding infection and subside spontaneously.

As has been emphasized above, the course and duration of chronic glomerulonephritis are highly varied and often unpredictable. While many patients fit a "classical" pattern, others partake of several. Many patients progress into the terminal stage without ever having experienced edema. An occasional patient develops clear-cut acute glomerulonephritis following respiratory infection, succeeded by a "nephrotic stage," which yields over a period of years to slowly progressive renal insufficiency and mounting hypertension. It is not usual, however, to observe this full sequence of events in one individual.

It is almost impossible, except in the most advanced cases, to offer an accurate prognosis from a single set of clinical observations and tests of renal function. Serial observations of the blood urea nitrogen or serum creatinine, phenolsulfonphthalein excretion, the degree of proteinuria and anemia, and the blood pressure may afford an estimate of the velocity and character of the process. *Probably because of the intensity of the associated vascular disease, the prognosis is much worse in glomerulonephritis with renal insufficiency than in pyelonephritis with azotemia of comparable severity.*

Although the blood in chronic glomerulonephritis may remain normal for years, anemia eventually develops in most patients by the time renal insufficiency makes its appearance. In patients in whom renal failure has developed only slowly, fatigue associated with anemia may be the presenting symptom. Severe anemia, recurrent after transfusions, implies a poor prognosis.

By the time azotemia has appeared, hypertension is present in most patients with glomerulonephritis, and as the disease approaches its terminus, blood pressure is elevated in all. When progression is very slow, both azotemia and mild hypertension may be borne without symptoms for years. Polyuria and nocturia may be the first signs of renal insufficiency. Loss of appetite and intractable nausea frequently bring the patient to the physician. Heart failure, anemia, and bleeding into the skin, mucous membranes, and gastrointestinal tract herald the final illness. The skin becomes dry, with a sallow tint,

the breath uriferous. Exophthalmos may be apparent. Hemorrhages and exudates appear in the fundi. The urinary output becomes progressively restricted. Fibrinous pericarditis or pleurisy may appear within a few weeks of death. Disorientation and coma mercifully precede the end.

At postmortem the kidneys are shrunken and fibrotic. Many glomeruli are completely hyalinized; in others there is only partial eccentric fibrosis, with varying degrees of adhesion of capillary loops to each other and to Bowman's capsule. The few glomeruli which are not injured are enlarged, as if stimulated to compensatory hypertrophy.

Differential Diagnosis. In patients with renal insufficiency, the possibility of other diseases of the kidney must be kept in mind. A history of acute nephritis with edema is helpful if present, but a detailed account of the illness should be obtained because what the patient refers to as "nephritis" may have been a urinary infection. Patients with primary hypertension usually do not develop renal failure unless the diastolic pressure is very high (over 130). Multiple myeloma and amyloid disease may mimic chronic nephritis in the middle-aged and elderly. Hypercalcemia may produce polyuria, azotemia, and anemia, all of which are potentially reversible.

Heavy proteinuria (over 2 to 3 Gm daily) is present in most patients with chronic glomerulonephritis (and the various other disorders which cause the nephrotic syndrome), but in few other renal diseases unless heart failure or malignant hypertension is present. Epithelial cell casts, red cell casts, and lipid droplets in the urinary sediment are useful in distinguishing the disease from pyelonephritis or primary nephrosclerosis. The kidneys are of equal size, usually without evidence of distortion of the calyces on pyelography and if small, are contracted symmetrically. The possibilities of lupus erythematosus, periarteritis, and bacterial endocarditis should be kept in mind. The author has seen a patient with endocarditis, without fever or murmurs, who presented as a case of chronic nephritis and died, undiagnosed, of progressive renal insufficiency.

Treatment. Restriction of activity is indicated in patients with heart failure, an acute exacerbation of nephritis with hematuria, or an intercurrent infection. Patients who feel well enough to be up and about should be permitted to do so and should be encouraged to lead normal lives. Diet should not be restricted except for the clear indications mentioned on p. 1477. Strenuous exertion leading to fatigue is probably best avoided. Since the day of Richard Bright, moving to a warm climate has been recommended to patients with nephritis by physicians living in cold climates; there is no evidence that it influences the natural history of the disease.

a few patients with normal blood pressure and mild asymptomatic proteinuria. Definite arteriosclerosis was described by Bell in 10.6 per cent of normotensive patients fifty to sixty years of age and increased in intensity and frequency in older age groups. It seems clear that renal arteriosclerosis may occur in the absence of systemic hypertension, though it rarely produces symptoms or signs. Such vascular changes may account for the moderate decrease in renal reserve often observed in elderly patients.

Clinical Features. Hypertension antedates proteinuria by many years in most patients with "essential" hypertension. When proteinuria does appear it is usually minimal. The urinary sediment is usually not remarkable, although microscopic hematuria and occasionally gross urinary bleeding may occur in the accelerated phase, when the excretion of protein may also increase to more than 4 Gm daily, reflecting widespread necrosis of glomerular capillaries. The anemia associated with advanced renal insufficiency occurs in some patients with nephrosclerosis as in other renal diseases, although the appearance of hypertensive neuroretinopathy with azotemia in the absence of anemia should suggest primary vascular disease. The patient with hypertension and uremia whose optic fundi are normal usually has glomerulonephritis or pyelonephritis. At the inception of the hypertensive process, renal blood flow is usually depressed more than glomerular filtration rate. The opposite is true in glomerulonephritis, but the difference has no important clinical significance.

The course of nephrosclerosis is extremely variable and cannot be predicted with regularity from the height of the blood pressure. Proteinuria and even mild azotemia may be borne without symptoms for many years. The abrupt change in course which marks the onset of the malignant phase is characterized by an increase in proteinuria, hematuria, and progressive azotemia. It is of interest that most cases in which this syndrome occurs have been known to have hypertension for less than 8 years.

The term "malignant hypertension" has been used variously to indicate (1) hypertension with papilledema, (2) hypertension with rapidly progressive renal insufficiency, or (3) hypertension with necrotizing arteriolitis. These arbitrary definitions should not be confused or allowed to obscure the facts in individual cases. Papilledema, hematuria, weight loss, advancing uremia, and necrotizing arteriolitis usually coexist in hypertensive patients, but it is not unusual for any of these features to be absent in the presence of the others. Thus, 23 per cent of 68 cases studied by Goldring and Chasis with excessively high diastolic pressure and rapidly advancing uremia did not have papil-

ledema. In some, the fundi showed only arteriolar narrowing without hemorrhages. Contrariwise, papilledema may be present in occasional patients at intervals for many months or even years without advanced renal involvement or necrotizing arteriolitis. In some patients the uremic syndrome appears over the course of a year or two, but hematuria and proteinuria remain minimal, and neuroretinopathy may never be present. Such cases are likely to have massive cellular intimal hyperplasia of the interlobular arteries with little necrotizing glomerulitis.

In addition to "primary" nephrosclerosis, the clinical syndrome of malignant hypertension may occur in the course of chronic pyelonephritis, glomerulonephritis, periarthritis nodosa, scleroderma, pheochromocytoma, and unilateral renal arterial occlusion.

NEPHROSIS

The nephrotic syndrome is not a single disease but a clinical constellation characterized by (1) massive proteinuria, (2) hypoalbuminemia, and (3) edema. Hyperlipemia is frequently but not invariably present. The term "nephrosis" is sometimes used by pathologists to indicate degenerative changes in renal tubular epithelium, but this definition should not be confused with the clinical syndrome under discussion.

Etiology. The nephrotic syndrome is primarily the result of diffuse injury to the glomerulus. In most cases the origin of the disorder is uncertain, although it presumably reflects an autoimmune reaction involving the glomerular basement membrane. It is of interest that many patients with the nephrotic syndrome have a history of allergic disease and may show striking eosinophilia. The injury may occur in the course of poststreptococcal glomerulonephritis or in association with amyloid infiltration of the glomeruli, diabetic intercapillary glomerulosclerosis, or lupus erythematosus. It may rarely be observed in allergic reactions to plant pollens, poison ivy, poison oak, or insect stings or as a manifestation of sensitivity to trimethadione or paramethadione. It may occur as a complication of secondary syphilis or malaria. The nephrotic syndrome has occasionally appeared in the course of treatment with mercurial diuretics and salts of gold and bismuth. Some of these cases may be examples of a hypersensitivity reaction; the evidence that heavy metals can cause massive albuminuria even in doses which induce tubular necrosis is not convincing. Massive proteinuria may result from the marked elevation in glomerular capillary pressure which follows thrombosis of the renal veins or constrictive pericarditis. Uncomplicated pyelonephritis or nephrosclerosis does not cause the nephrotic syndrome.

variety; in the former group rapidly progressive vascular disease occurs terminally in 15 to 20 per cent. A large proportion (estimates vary widely from 10 to 75 per cent) of all patients dying of malignant hypertension are found to have kidneys characteristic of atrophic interstitial pyelonephritis ("pyelonephritis lenta" of Saphir). Accurate estimates of the role of bacterial infection in this syndrome are limited by the nonspecific nature of many of the pathologic changes.

In general, glomerular filtration and renal blood flow decline together and proportionally as the disease progresses. As might be expected, there is usually more disparity between the function of the right and left kidneys than is generally the case in diffuse diseases of the kidney like glomerulonephritis or nephrosclerosis. Maximum concentrating ability tends to become impaired earlier in the course than in patients with chronic glomerulonephritis. Occasional patients with advanced azotemia may excrete a urine hypotonic to plasma, even when dehydrated. Many patients are unable to conserve sodium on a low-salt diet, even when only mild azotemia is present. Polyuria and nocturia are prominent in such cases. Hyperchloremic acidosis as a result of impaired renal excretion of acid and reabsorption of bicarbonate is more often a feature of chronic pyelonephritis than of glomerulonephritis. Proteinuria is usually less than 2 Gm (rarely as much as 4 to 5 Gm) daily.

Careful examination of the *urinary sediment* is often the key to diagnosis. Leukocytes may be numerous or infrequent, but the appearance of *white cell casts* should alert the physician to the possibility of chronic pyelonephritis. Bacteria may be present on the fresh stained smear but, together with pus cells, often appear intermittently or not at all in the chronic atrophic stage of the disease. It should be noted that the urine sediment may be normal and, especially with a dilute urine of fixed specific gravity, that no albuminuria, or only a trace, may be detected. Although characteristic distortion, flattening, and reduction in size of the renal pelvis, frequently without ureteral changes, are usually found on pyelography (p. 1038), their absence does not rule out chronic pyelonephritis.

When pyelonephritis is not accompanied by hypertension, the course may be prolonged and compatible with comfortable and useful life even after considerable encroachment upon renal function. In perhaps no other disease of the kidneys can fluctuations in renal function be so marked or so frequent. During acute infections or episodes of dehydration, renal decompensation may progress to the stage of advanced uremia; yet the patient may be able to recover and carry on with adequate though impaired renal function for years. Nonspecific complaints of fatigue, anorexia, and weakness

often remit remarkably when the urine is sterilized by an appropriate course of antibiotics and if acidosis, dehydration, and salt depletion are adequately treated.

The problem of *recurrent infections* with resistant bacteria is an important and unsolved one. An effort should be made to treat urinary tract obstruction and to improve bladder emptying, when residual urine is present. Reducing the bacterial population of bladder urine by the prolonged administration of urinary antiseptics may offer some hope for halting the indolent progression of the disease, in this connection, however, acidifying agents are likely to be ineffective and harmful in patients with azotemia.

It should be emphasized that, even in cases where one kidney appears small and the other normal in size, pyelonephritis is in most instances bilateral. Nephrectomy which is undertaken in the hope of eradicating the disease is generally doomed to failure. Excision of hydronephrotic, pus-filled renal shell will, however, sometimes permit a successful therapeutic attack on infection in the opposite kidney with a carefully chosen antibiotic given in adequate dosage for a long period of time.

NEPHROSCLEROSIS

Definition and Pathology. Although early in the course of "essential" hypertension there may be no morphologic changes in the kidney at all, structural alterations in the small arteries and the arterioles are almost always present in the kidneys of patients who die in the course of hypertensive disease. In about 10 per cent of such patients the changes are severe enough to produce marked renal insufficiency. Large and medium-sized arteries show a variable degree of intimal thickening. This change is more ubiquitous and more severe in the small arteries and arterioles. In addition, an eosinophilic hyaline thickening frequently involves the entire wall of arterioles and prearterioles. These changes may lead to mild generalized atrophy of the cortex with focal scars. Hyalinized glomeruli are a conspicuous microscopic feature.

In patients who die with rapidly progressive, "malignant" hypertension, especially after renal insufficiency has appeared, there is often intense intimal hyperplasia of the medium-sized and small arteries, so that the lumen may be substantially reduced. Necrosis of the preglomerular arterioles is present, which frequently extends into the glomerular tufts. There may be hemorrhages into Bowman's space and occasional crescent formation.

It is not generally realized that similar but less intense changes may be found at postmortem in patients without systemic hypertension. Arteriosclerosis may be observed in the renal biopsies of

syndrome, and blood nonprotein nitrogen is not elevated. Azotemia gradually develops, together with a fall in filtration rate and filtration fraction, in patients with progressive nephritis. In others renal function may remain normal, despite edema, for years, but may be depressed transiently, particularly during or immediately following infections. Tubular functions such as concentrating ability and phenolsulfonphthalein excretion are generally normal. Occasionally aminoaciduria or renal glycosuria is observed, presumably as a result of interference with proximal tubular reabsorption.

The term "pure" or "lipoid" nephrosis has been used in the past to designate patients with the nephrotic syndrome without hematuria, hypertension, or azotemia and without discernible etiology. Although prognosis is clearly better the longer patients escape hypertension or renal insufficiency, the author believes that it serves no useful purpose to classify such patients in a separate category from others with membranous glomerulonephritis and the nephrotic syndrome, since glomerular lesions are observed in all by electron microscopy and some develop hematuria, high blood pressure, and azotemia later in their course.

Pathologic Physiology. Much evidence indicates that the glomerular basement membrane is abnormally permeable to proteins. Those of low molecular weight and small size, like albumin, are lost into the urine in greatest quantity. Although it is conceivable that failure of the renal tubular epithelium to reabsorb protein might contribute to proteinuria, the massive amounts of protein excreted by some nephrotics and the striking increase in protein excretion observed following infusions of concentrated serum albumin suggest that increased glomerular permeability is the major determinant of the nephrotic syndrome. Indeed, there is good reason to believe that tubular reabsorption of protein is increased. There is no evidence (except in nephrosis associated with multiple myeloma) that abnormal proteins appear in plasma or urine. Hypoalbuminemia is chiefly a result of the extensive urinary losses of this protein; its synthesis is normal or even increased. In addition, in some patients the rate of catabolism of albumin is accelerated in a manner similar to that observed in a variety of acute injuries or infections. Associated with the reduction of serum albumin there is usually marked wasting of tissues, which may be clinically evident only after the edema disappears. Balance studies carried out in nephrotic patients during refeeding with high-protein, high-calorie diets suggest that, for every gram of protein added to the plasma, 20 to 100 Gm of tissue protein must be incorporated in tissue.

The decrease in plasma albumin and consequent fall in the oncotic pressure of plasma results in an

increased transudation of fluid from the blood stream to extravascular spaces. Plasma volume tends to fall. The reaction of the kidneys to these events is to diminish the excretion of sodium and of water, as in many other situations where the integrity of the effective circulating blood volume is threatened. The mechanism by which this is accomplished involves the greatly augmented secretion of aldosterone by the adrenal cortex, although the exact nature and pathway of the afferent stimulus for this adjustment are not yet clear. Changes in glomerular filtration rate may also be contributory in some patients. The primary role of sodium in the production of nephrotic edema is demonstrated by the fact that, when administered without salt, water may be excreted normally. When the intake of sodium is continued, it is retained by the kidneys and sequestered with water in an expanded interstitial fluid. Despite edema, plasma volume remains normal or low. If albumin is added to the blood stream in increased amounts, or its rate of loss is diminished, the sequence of events will be reversed and diuresis will ensue.

When the quantity of circulating albumin is increased in a nephrotic patient, plasma volume is expanded by dilution with extravascular edema fluid, thereby minimizing the expected rise in albumin concentration. For this and other reasons, diuresis and edema formation need not be correlated with the exact concentration of albumin in the serum.

The pathogenesis of the hyperlipemia associated with the nephrotic syndrome is not clear. Serum cholesterol, phospholipids, and triglycerides usually are all increased in nephrotic patients. The rise in triglycerides may be so marked that the serum is milky. At least one reason for the elevation in serum cholesterol is its increased solubility in fatty serum, though increases in serum cholesterol may also be observed in the absence of lactescent serum and even when serum triglycerides are normal. Decreases of cholesterol and lipid phosphorus frequently coincide with periods of especially severe anorexia or vomiting; increases with periods in which appetite is good. Nevertheless, the most intense lipemia may be observed in wasted patients with extreme hypoproteinemia and the most massive edema. Though hyperlipemia usually disappears when elimination of edema marks regression of or recovery from the disease, it may persist in rapidly progressive cases despite advanced azotemia and hypertension.

Hyperlipemia is not secondary to increased synthesis of fat or to increased fat in the diet, but appears to be caused by a defect in fat transport. The removal of triglycerides from the blood stream normally involves their hydrolysis by lipoprotein lipase, with the liberation of free fatty acids to the

Pathology. Histologic examination of the kidneys reveals a spectrum of morphologic changes which vary in individual patients as well as from case to case. Some glomeruli may appear quite normal by light microscopy, but under the electron microscope the foot processes of glomerular endothelial cells are seen to be broadened and smudged. (There is evidence that this particular change may be a result of proteinuria, rather than its cause.) When the lesion is more advanced, definite spotty or diffuse thickening of the basement membrane is apparent by the usual histologic techniques, often with little or no cellular infiltration or endothelial proliferation, hence the term *membranous glomerulonephritis*. In other patients there is an increase in glomerular cellularity, and occasional capsular adhesions may be observed. In still other cases, the process of basement membrane thickening has gone on to fusion and simplification of the glomerular loops and to partial or complete hyalinization of some glomeruli. In all instances, the proximal tubular cells are swollen with intracytoplasmic droplets and vacuoles, some of which are doubly refractile. It is not clear whether these represent protein and lipid reabsorbed in huge quantities from the glomerular filtrate or that deposited from the blood in injured cells.

Clinical Features. The disease is commoner in children than adults and is more frequent in males, but may affect any age and either sex. Occasionally a respiratory infection may have occurred just before the onset, but it is uncommon to find evidence of preceding streptococcal infection. The patient usually presents himself because of the insidious onset of edema. This is often particularly noticeable in the face because of the absence of orthopnea. The edema is characteristically soft and pits easily. Ascites and pleural effusions are frequently present, but pulmonary edema does not occur without heart failure. Though edema may be the only manifestation, other symptoms may be present, vaguely suggestive of the extensive depletion of body proteins that hypoalbuminemia betokens. Loss of appetite is frequent, although not so common as in post-streptococcal glomerulonephritis. A previously active child may feel tired and rundown. Amenorrhea or some irregularity in menses is the rule in women. The course is sometimes punctuated by unexplained episodes of abdominal pain, vomiting, and diarrhea.

The blood pressure is often normal; the heart is generally not enlarged in the absence of hypertension. The fundi are normal except when diabetic glomerulosclerosis is the cause of the disorder. The skin looks puffy and pale; there may be a mild normocytic anemia, but the hematocrit is usually higher than the pasty appearance of the patient suggests. Mild generalized osteoporosis is frequently observed, especially in children.

The daily urine usually contains more than 4 to 5 Gm of protein, chiefly albumin, but significant quantities of α_1 -, β -, and γ -globulins are found as well. Some nephrotics excrete as much as 20 to 30 Gm of protein each day. The serum proteins are grossly reduced, especially the albumin and, less predictably, the γ -globulin fraction. Serum γ -globulins are said to be normal in the nephrosis caused by lupus erythematosus or amyloid disease; they may also be found within normal limits, in the author's experience, in the nephrosis associated with membranous glomerulonephritis. α_2 -Globulins are generally elevated, but this occurs in many chronic diseases. Serum albumin is usually below 2.0 to 2.5 Gm per 100 ml when edema is present and with massive edema is frequently below 1.0 gm per 100 ml. It should be noted that conventional salting-out techniques frequently overestimate the concentration of serum albumin at low levels of this component. The over-all increase in the lipid-carrying globulins conceals a reduction in the concentration of the smaller metal-carrying proteins, transferrin (iron) and ceruloplasmin (copper). Serum complement is decreased in membranous glomerulonephritis, although not in diabetic glomerulosclerosis. Serum calcium is low, entirely as a result of a decrease in the fraction bound to albumin. Plasma fibrinogen is elevated, and the sedimentation rate is greatly accelerated. The cholesterol, phospholipids, and triglycerides in the serum are usually elevated, and the serum is often lactescent. The low-density β -lipoproteins, to which these molecules are attached, increase in concentration. When caloric intake has been low and nutrition poor, however, serum cholesterol and triglycerides may be normal. This is frequently the case in instances of the nephrotic syndrome caused by lupus erythematosus and Kimmelstiel-Wilson disease.

The basal metabolic rate is usually low, perhaps as a result of malnutrition and, in some cases, of failing to correct for edema fluid in estimating weight. The impression of hypothyroidism may be strengthened by a puffy face and pasty appearance, by an elevated serum cholesterol, and by the decrease in serum precipitable iodine, which, however, is a consequence of the low concentration of thyroxin-binding proteins in the serum, rather than of impaired thyroid function. Treatment with thyroid produces no improvement.

The urinary sediment is filled with granular and epithelial cell casts, and casts in which highly refractile lipid droplets are embedded. Fat bodies may be seen in the urine even when the serum cholesterol is normal. Red blood cells are often absent, but many patients show some degree of continuous or intermittent microscopic hematuria.

Glomerular filtration rate is frequently normal or above normal early in the course of the nephrotic

there is usually some subjective increase in feeling of well-being, and over many months a slow rise in plasma albumin. The increase in blood urea which invariably occurs on a high-protein diet reflects the additional amount of urea presented to the kidney for excretion, rather than deterioration of renal function. Proteinuria may also increase when serum albumin rises.

Adrenal steroids or ACTH produce improvement in about 75 per cent of children and a somewhat lower proportion of adults with the nephrotic syndrome. Dosage schedules vary, but a reasonable plan is to give 60 to 80 mg prednisone or 40 to 80 units zinc corticotropin suspension daily until a remission occurs or treatment has been continued for 4 weeks. Daily doses of prednisone lower than 40 mg are often insufficient to control proteinuria, while amounts higher than 80 to 100 mg are unnecessary. Remission generally requires the development of Cushing's syndrome. If no improvement is observed after a month of treatment with high doses of adrenal hormones, further prolonged treatment is not likely to produce a cure, although the patient may improve spontaneously. Diuresis sometimes occurs when steroids are discontinued, without diminution in proteinuria, but this is a nonspecific and transient response probably ascribable to temporary suppression of endogenous adrenal secretion. The earliest sign of a therapeutic effect upon the disease process is a diminution in the number of grams of protein excreted daily. This may be observed as early as 2 days after the beginning of treatment, but usually after 10 days to 2 weeks. During the initial stages of therapy, blood urea may rise because of the increased catabolism of protein induced by steroids. Glomerular filtration rate, however, usually is unchanged or increased by steroid treatment, so that serum creatinine does not rise and may even decrease. Once begun, the decrease in proteinuria proceeds rapidly, succeeded by a rise in serum albumin and loss of edema. Proteinuria may disappear completely or diminish to a constant low level. After no further improvement can be detected, the dose of steroids is gradually reduced over a period of about 4 to 6 weeks. If the drug is interrupted at this time, some patients will continue in remission indefinitely, but many relapse at varying intervals up to years following cessation of treatment. In an attempt to prevent such recurrences, it is common practice to keep patients on some maintenance schedule of steroid, administered either daily or 3 to 4 days per week, in a dose intermediate between that originally required to induce remission and that at which proteinuria occurs. Serial biopsy studies suggest that, when successful, such treatment decreases cellular proliferation in glomeruli and arrests the usual pro-

gression from thickening of capillary basement membrane to obliteration of the glomerular capillary.

Complications of steroid treatment include hypertension, muscular weakness and cramps, peptic ulcer, potassium depletion, diabetes, and osteoporosis (p. 626). Striae which break down and become infected may be most troublesome in edematous nephrotic patients. The leukocytosis which regularly accompanies administration of large doses of steroids may confuse proper evaluation of infection. Hyponatremia associated with rising serum potassium and high blood pressure may be observed in occasional unresponsive patients who have received large doses of hormone for long periods of time. The advantages of a proper dietary regimen must not be neglected in the course of treatment with steroids.

Patients with amyloid disease or the Kimmelstiel-Wilson syndrome do not respond to treatment with steroids, nor do those with the nephrotic syndrome occurring in the course of acute poststreptococcal glomerulonephritis. Treatment of nephrosis complicating lupus erythematosus is discussed under that heading.

Except for helping to rule out amyloid disease and diabetic nephropathy, renal biopsy has so far not proved helpful in predicting which patients will improve with steroid therapy. It is clear that the presence of some hyalinized glomeruli, cellular proliferation, or membranous thickening of capillary loops does not rule out the possibility of a remission with steroids. A favorable response may be observed in the presence of mild hypertension, microscopic hematuria, and even moderate azotemia.

Diuretics may be used to control edema in conjunction with sodium restriction, whether or not adrenal steroids are prescribed. Mercury is not contraindicated unless azotemia is present, but should not be administered repetitively if the initial few doses do not produce a diuresis. The action of diuretics may often be enhanced by infusions of albumin, plasma, or dextran. These agents raise the oncotic pressure of plasma and expand plasma volume temporarily but are rapidly lost into the urine through the leaky glomerular filter. Diuresis is not an end in itself; a little edema is often to be preferred to the complications of too-vigorous diuretic therapy.

Nitrogen mustard has been reported to induce transient remissions in proteinuria in patients with the nephrotic syndrome, but there is no evidence of any long-term benefit.

In the rare forms of the nephrotic syndrome caused by secondary syphilis or malaria, specific antiluetic or antimalarial treatment usually results in complete cure.

circulation. Of the small quantity of unesterified fatty acids normally present in serum, most are transported bound to albumin. Infusion of albumin into patients or animals with the nephrotic syndrome produces an immediate fall in serum lipids, often but not always to normal, and in general in nephrosis, elevation of all the lipid components of serum tends to be inversely proportional to the level of serum albumin. It has been postulated that, when the concentration of albumin falls, the hydrolysis of plasma triglycerides is inhibited by the absence of adequate plasma albumin with available binding sites for fatty acids, thereby "trapping" neutral fat in the plasma. Other factors necessary for normal transport of fats may also be deficient. It is of interest that infusions of dextran, which restore the colloid osmotic pressure of serum, result in a fall in plasma lipids in patients with nephrosis. Patients who have hypoalbuminemia for other reasons may not demonstrate the marked hyperlipemia and hypercholesterolemia of nephrosis. In such disorders decreased intake or absorption of food may play a role in muting this manifestation, as it presumably does in some patients with the nephrotic syndrome.

Natural History and Prognosis. The clinical course of the nephrotic syndrome is highly variable, depending to some extent upon the nature of the underlying disease. The following discussion will be concerned with nephrosis of uncertain etiology characterized by glomeruli which appear "normal" on light microscopy or have the morphologic changes of membranous glomerulonephritis.

A distinction should be made between the course and prognosis of the disease in children and in adults, the prognosis being appreciably better in children. Before the introduction of steroid treatment, the disease was eventually cured or arrested in about 50 per cent of children, although 40 per cent died within 5 years of onset. By contrast, in only one-quarter of adults with the nephrotic syndrome was a cure or spontaneous arrest of the disease observed which lasted longer than 2 years. Spontaneous diuresis is occasionally observed to follow measles, but in other instances bacterial or viral infections appear to induce a relapse. Before antibiotics were available, deaths from infections, frequently with the pneumococcus, were common. Erysipelas, pneumonia, septicemia, and peritonitis can now be avoided or successfully treated, and as a result, early mortality has been sharply reduced. The disease is frequently remittent, with intervals in which proteinuria is decreased or absent, and cases are occasionally seen in both children and adults in whom episodes of proteinuria and edema are separated by intervals of many years. Repeated remissions and exacerbations are uncommon, on the

other hand, in the course of the nephrotic syndrome which follows in the wake of acute hemorrhagic glomerulonephritis. Persistent hypertension and azotemia are associated with a poor prognosis. Mild elevation of blood urea, intermittent hypertension, and microscopic hematuria have been observed in patients who improve spontaneously, as well as in those who develop progressive impairment of renal function. About one-quarter to one-third of children and one-half to two-thirds of adults with nephrosis develop progressive renal insufficiency and increasing hypertension and die of heart failure or uremia, generally within 2 to 5 years. In others, proteinuria is diminished but seldom disappears, renal function remains stationary at a level near normal, and the patient is asymptomatic, with or without hypertension. In patients whose dietary intake of protein is high, considerable proteinuria may be compatible with only moderate reductions of serum albumin, without edema. Edema may be precipitated by intercurrent infections which decrease appetite and promote the breakdown of protein, and may disappear when these disturbances are removed, without alterations in the urinary excretion of albumin. With the development of advancing glomerular hyalinization, proteinuria frequently diminishes in amount, serum albumin rises, and edema disappears as azotemia progresses.

Treatment. Although a few days in bed may help to mobilize edema, there is no indication for prolonged bed rest. Hospitalization is indicated at the onset of the disease to confirm the diagnosis and to obtain base-line studies but need not be prolonged.

The diet should be low in sodium and high in protein. Except in the presence of hyponatremia, water should not be restricted. Very low sodium diets (200 mg) are unpalatable, although the development of "sodium-free" milk and milk powders has made a satisfactory high-protein, low-salt diet more feasible. Sodium restriction should, however, be considered an emergency measure to control edema; it is not indicated during convalescence from the nephrotic syndrome or when edema is minimal. A high consumption of protein, together with adequate calories, leads to steady replenishment of wasted tissues. Since the goal is to restore body proteins, not simply to prevent further wastage, additional intake of protein above the normal requirement of 1 Gm per kg per day, plus urinary losses, is of importance. If the additional protein is to be utilized, sufficient calories must be given. The proportion of fat and carbohydrates is determined, as a practical matter, by the composition of the supplements of milk or milk powder. There seems to be no great advantage to restriction of fat. With such liberal intake of protein and calories,

ACUTE TUBULAR NECROSIS—ACUTE RENAL FAILURE

The term *acute renal failure* has been used loosely to include all forms of acute urinary suppression, generally secondary to acute parenchymal damage. *Acute tubular necrosis* (or lower nephron nephrosis) indicates the clinical and pathologic syndrome which results when renal excretory function is temporarily lost because of renal tubular degeneration caused by renal ischemia or toxic agents.

Pathology. Microdissection studies reveal two types of lesions. When specific toxins (bichloride of mercury, carbon tetrachloride, diethylene glycol) have been administered, there is diffuse necrosis of the proximal tubular cells, while the basement membrane of the proximal tubules, from which a new lining may regenerate, is spared. The lesion caused by ischemia, on the other hand, occurs at random among nephrons and in any part of a nephron. It consists of complete destruction of limited stretches of tubular lining scattered along the course of an otherwise well-preserved nephron. The basement membrane is frequently disrupted. During recovery from both types of lesions, mitotic cells may be seen. Except in cases in which extremely severe and prolonged ischemia has produced renal cortical necrosis, the glomeruli are intact. Casts packed with degenerating epithelial cells and hemoglobin are seen in the straight tubules of the medulla. The most important inference to be drawn from the nature of the pathologic process is that, should the patient survive his other injuries, the renal lesions will be repaired.

Etiology and Pathogenesis. Acute tubular necrosis typically occurs in a setting of sudden injury or illness usually associated with shock or with intense renal vasoconstriction. Even those cases which follow the administration of known tubular toxins are generally aggravated by vascular collapse and renal ischemia. Nevertheless, perhaps because of difficulty in recognizing and quantifying the ischemic state, the etiology may go undiagnosed in as many as 25 per cent of patients. Common causes include hemolysis and hypotension following extensive burns, rapid hemorrhage or hypotension on the operating table, bacteremic shock, crushing injuries in which the toxic effects on the kidney of myoglobin are added to those of vasoconstriction and shock, and intravascular hemolysis from transfusion of mismatched blood as well as rapid infusions of distilled water (e.g., during transurethral prostatectomy). Following operations on the heart, aorta, or great vessels during which renal circulation is interrupted, some degree of acute tubular necrosis is almost invariable. Pregnancy appears in some way to predispose to ischemic renal insults; in a large proportion of most published series, acute

renal failure followed placenta previa, septic abortion, post-partum hemorrhage, or eclampsia. Other conditions which have triggered tubular necrosis include sudden defervescence following salicylate administration and status epilepticus. Acute renal failure is the most important cause of death in epidemic hemorrhagic fever.

Tubular necrosis resulting from many poisons is enhanced by prior dehydration and tends to be prevented by infusions of saline if these are given before the noxious agent is presented to the kidneys. Paradoxically, healthy renal tubules may be more susceptible to certain types of injury than are poorly functioning ones. A dose of uranium nitrate that induces acute tubular necrosis in a healthy dog may not interrupt the urine flow when given again to the same animal during the diuretic phase of early recovery from renal insufficiency. The role of free pigments derived from blood and muscle in the pathogenesis of tubular necrosis is not clear. Infusions of purified hemoglobin decrease renal blood flow and may be toxic to tubular cells. In addition, intravascular hemolysis may liberate other vasoconstrictor substances which promote renal ischemia.

Pathophysiology of Anuria. The formation of casts which occlude the renal tubular lumina may play some part in the pathogenesis of oliguria. In most patients, however, casts appear to be a result of diminished urinary flow rather than its cause. An exception is the renal failure which not infrequently follows dehydration in multiple myeloma and which may be characterized by extensive gel formation by abnormal proteins in renal tubules.

Following the acute renal ischemia which usually initiates tubular necrosis, renal blood flow is decreased to approximately one-third to one-half normal during the first days of oliguria. It is not clear whether or not this precludes any appreciable persistence of glomerular filtration. Increased interstitial pressure secondary to edema probably reduces renal blood flow and filtration rate and collapses tubules. The presence of interstitial edema may be inferred from the increase in the weight of the kidneys during acute tubular necrosis. Experimental measurements of wedged-renal vein pressure and of pressures at the end of a fine needle inserted directly into the kidneys have, however, not shown elevation. The pressures may, nevertheless, have been sufficient to collapse renal tubules which were distended with less than the normal pressure derived from glomerular filtration and urine flow. In any case, much fluid which is filtered at the glomerulus must leak back into the substance of the kidney through the widely scattered disruptions in the denuded tubular basement membranes. As tubular repair proceeds and these leaks are mended, urinary flow improves.

hausted, semicomatose patients. Common predisposing factors are loss of ability to cough or change position, drying of pharyngeal mucosa from constant mouth breathing, and the aspiration of inspissated mucus plugs or vomitus. Healing of surgical wounds seems to be impaired, and infection or dehiscence of incisions is common. Infection of the urinary tract, sometimes silent but often with fever, flank pain, and gram-negative septicemia, frequently results from the use of indwelling catheters or repeated instrumentation of the bladder.

Neurologic manifestations are common, the two most important being coma and convulsions. Hyponatremia may be responsible for somnolence or seizures early in the course of acute renal failure and may be corrected by hypertonic saline, with proper regard for the complications of overhydration and heart failure. Hypocalcemia may also predispose to convulsions, as may too-vigorous administration of alkali without accompanying calcium in the treatment of acidosis. Seizures may be focal in nature or generalized; some presumably have a vascular basis. They sometimes appear to be triggered by vomiting, heart failure, or the rapid changes in body volume and composition which may accompany the onset of profuse diuresis.

Anemia usually appears in the second week, even without bleeding, presumably as a result of a mild increase in erythrocyte destruction and a deficiency in erythroid hyperplasia. Defects in hemostasis are commonly encountered and include thrombocytopenia, abnormal prothrombin consumption time, and other less well-defined coagulation deficiencies.

In some patients tubular necrosis is not associated with oliguria, or the period of diminished urine flow is so short as to pass unrecognized. The urine volume in such cases is, however, not flexible or responsive to body needs and may be fixed at perhaps 800 to 1,200 ml per day. The diagnosis may only be appreciated when the blood urea nitrogen is seen to rise at the rate of 15 to 20 mg per 100 ml per day and when the patient becomes edematous owing to retention of fluids in excess of the excretory capacity of the kidneys. Unlike most other edema-forming states, the urine in such cases contains sodium in a concentration higher than 20 to 30 mEq per liter and the concentration of total solutes does not differ significantly from that of plasma.

After the first few days of oliguria the urine loses its grossly bloody character and becomes clear, increasing slightly in amount every day. The onset of tubular recovery is usually heralded by an increase in daily urinary output to 400 ml. At this point the urine usually contains very little protein, although the sediment may still contain red cells and many large dark hematin casts. Further increases in flow are sometimes dramatic, the urine

volume increasing by 50 to 100 per cent each day until polyuria exceeds 3,000 ml daily. In other patients daily urine volume only gradually approaches a liter over the course of a week or two. If brisk diuresis is never achieved, the blood urea falls only slowly or not at all, and the urine contains more than 3 to 4 Gm of protein per liter, cortical necrosis must be suspected. The blood urea usually continues to rise for several days after urinary output exceeds 1 liter per day, until the excretion of urea exceeds its production. In addition, during the early diuretic phase of recovery, hyperpotassemia, congestive heart failure, and convulsions may complicate the clinical picture. Pylonephritis frequently makes its appearance at this time, and death from infection, when it occurs, is commonly during diuresis. The onset of the diuretic phase, therefore, should not cause the physician to relax his vigilance.

Diuresis is usually associated with a striking weight loss, representing fluid accumulated during the period of oliguria. The urinary concentration of sodium usually varies from 50 to 75 mEq per liter. Some of the excreted sodium is derived from edema fluid, but if the remainder is not replaced, hyponatremia and dehydration may ensue. Elevated levels of serum sodium and chloride are observed during the diuretic phase when water replacement is inadequate and the patient is allowed to dehydrate himself through the obligatory excretion of a large volume of urine containing sodium at a lower concentration than plasma. Occasionally, urinary losses of potassium so greatly exceed intake that hypokalemia is noted. Once established, diuresis proceeds smoothly unless interrupted by urinary obstruction or shock, and azotemia regresses over the course of 1 to 3 weeks. If diuresis is interrupted by a second period of oliguria and rising blood urea, obstruction to bladder or ureters must be seriously considered.

After discharge from the hospital, anemia sometimes persists for weeks or months, gradually disappearing without benefit of hematinics. Muscle weakness and joint stiffness slowly improve. Chronic pyelonephritis may be a major problem. Although azotemia generally disappears and renal function may be restored, renal blood flow and glomerular filtration rate usually do not return completely to normal. Hypertension is not a sequel in those who recover from acute tubular necrosis, though it may complicate the unusual case of cortical necrosis who survives anuria.

Differential Diagnosis. The physician is frequently faced with an oliguric patient who has just passed through an episode which may have produced tubular necrosis, but in whom the diagnosis is not yet established. Vigorous treatment of shock, congestive heart failure, dehydration, or hyponatremia frequently resolves the question by promot-

Clinical Features. In the majority of cases, acute tubular necrosis is characterized by a period of oliguria and increasing clinical and chemical evidence of renal failure, lasting from a few days to as long as 3 weeks, and averaging about 10 to 14 days. This is succeeded by a period of relatively rapid return of urine flow and improvement in renal function, while water and metabolites accumulated during the oliguric phase are excreted.

During the first few days of *oliguria*, the clinical picture is dominated by the underlying illness. The urine is scanty and usually bloody. Although the specific gravity may be high owing to the presence of red cells and protein, its freezing point is close to that of plasma, and the sodium concentration is usually over 50 mEq per liter. Traces of glucose may appear in the urine. Complete anuria for more than 24 hr is infrequently encountered, though it is common to see less than 30 to 40 ml of urine for several days. If the condition is not recognized early, edema and/or hyponatremia may develop as a result of the unrestricted intake of fluids. If this pitfall is avoided and shock is successfully treated, the only symptoms during the first week may be lethargy and nausea. The latter is related partially to the development of metabolic acidosis. Fever is uncommon after the first day or two. Leukocytosis, on the other hand, is the rule, with or without infection. It should be emphasized that severe systemic symptoms during the first several days are usually *not* a result of renal failure but of associated conditions.

Serum amylase and lipase may be elevated as a result of renal failure per se, without implying active pancreatitis. Blood urea nitrogen rises at a rate influenced by the degree of tissue necrosis and endogenous protein catabolism. In a chronically ill patient who has had a mismatched transfusion, a daily rise of 20 mg per 100 ml might be expected, increments of 50 mg per 100 ml per day in blood urea nitrogen are not uncommon in previously healthy persons who have undergone severe crushing injuries or overwhelming infections. Disproportionate elevations in serum phosphate or serum creatine have been proposed as diagnostic aids in the detection of devitalized tissue.

During the second week of *oliguria*, nausea, weakness, and somnolence become more prominent as azotemia mounts, acidosis increases, and the serum potassium becomes elevated. Thirst is commonly present and may be severe, although the serum sodium is frequently depressed, extracellular fluid volume is expanded, and there are no clear signs of shock or heart failure.

Cardiovascular complications arise in most patients during the oliguric phase of acute renal failure. Although overhydration is perhaps the most important cause of pulmonary edema, signs of pul-

monary congestion and cardiac failure may appear even in patients who have been optimally treated. Pulmonary edema may develop in the absence of hypertension and without peripheral edema. Diastolic hypertension becomes evident in about 25 per cent of patients during the second week of *oliguria*. The fundi, however, remain normal. In exceptional instances in which the tension is very high, arteriolar necrosis develops. Arrhythmias are frequent and are not necessarily associated with potassium intoxication or removal. Pericarditis may develop but does not have the grave prognosis attached to its appearance in chronic renal disease. It may be extremely painful and simulate intraabdominal disease. Occasional patients die of acute cardiorespiratory failure characterized by apprehension, tachypnea, inconstant respiratory wheezing, progressive cyanosis, and hypotension. At postmortem no evidence is found of pulmonary emboli, and the lungs show mild to moderate terminal congestion.

Potassium intoxication may arise because of the liberation of large amounts of potassium from injured or infected muscle, intravascular hemolysis, or hematomas. It rarely occurs in the course of renal failure following a postoperative hemorrhage or transfusion reaction, in which the rate of tissue catabolism is not increased and in which proper attention has been paid to hydration and caloric needs from the inception of the disease. The rate of rise of the serum potassium reflects the catabolic response of the patient to injury. In addition, anoxia, acidosis, and dehydration are important determinants of the rate of loss of potassium from cells. The chief dangers are cardiac arrhythmias and standstill. Electrocardiographic abnormalities rarely occur when the serum potassium is below 7 mEq per liter but are almost always present above 9 mEq per liter. As serum potassium rises, the T waves become high and peaked. The P wave disappears, the QRS complex becomes broad and slurred, bradycardia and arrhythmias ensue, and the ventricular complexes finally resemble those of ventricular tachycardia. These changes may be modified by digitalis and by correction of acidosis and hyponatremia. Susceptibility of the heart to vagal standstill is enhanced, and sudden death may occur, even in the absence of characteristic electrocardiographic changes of potassium intoxication. The electrocardiogram, though a necessary adjunct, is not an entirely satisfactory replacement for the flame photometer in evaluating such situations.

Infection is the most frequent complication of acute tubular necrosis and the most common cause of death. Sepsis may often be overlooked because of confusion with uremic symptoms. Pulmonary and blood stream infections with "hospital" organisms, particularly the staphylococcus, are frequent in ex-

may be indicated, especially when overhydration is not apparent and congestive heart failure is not present.

Potassium intoxication may be prevented in many cases by proper attention to requirements for water and glucose, as well as by the prophylactic oral administration of a teaspoon of potassium-exchange sulfonic resin, sodium polystyrene sulfonate (Kayexalate, Winthrop), three times daily. Larger amounts of the latter may be used if necessary. One tablespoon four times daily by mouth or enema usually serves to reduce an elevated serum potassium by 1 or 2 mEq every 24 to 48 hr. If hyperpotassemia is associated with acidosis, it may frequently be brought under control by infusions of sodium bicarbonate or sodium lactate. Infusions of hypertonic glucose solutions, with or without insulin, have a similar but more transient effect. The deleterious action of potassium on the heart may to some extent be counteracted by infusions of calcium or by the administration of digitalis. If hyperpotassemia cannot be controlled by these measures, artificial dialysis is indicated.

Heart failure should be treated with digitalis in the usual doses. Artificial dialysis with the removal of several kilograms of edema fluid by ultrafiltration may be dramatically effective in relieving pulmonary edema. Testosterone propionate or norethandrolone, 25 to 50 mg daily, may be given during the first 2 weeks in an attempt to reduce nitrogen breakdown. Its action in this regard, however, is frequently overwhelmed by the intense catabolic reaction to acute injury.

Scrupulous care should be taken to avoid infection. After the diagnosis is established, an accurate estimate of the daily output may be obtained by catheterizing the patient, using sterile precautions, only once in 24 or 48 hr, thus dispensing with an indwelling bladder catheter. As the urinary volume reaches a significant level, most patients will be able to void spontaneously. It is desirable for hospital personnel handling the patient to wear mask and gloves. In alert patients, deep breathing and forced coughing should be stressed to avoid atelectasis. Tracheotomy should be considered early if there is difficulty in handling bronchial secretions. Careful mouth care with prevention of crusting and ulceration is important in avoiding parotitis and aspiration of infected material. Prophylactic administration of antibiotics should be avoided.

Several procedures have been proposed to substitute for renal function during acute renal failure. Irrigation of the stomach, intestines, or peritoneum may remove significant quantities of urea and potassium, although these procedures are less effective than hemodialysis. In an artificial kidney, blood rendered incoagulable by heparin is pumped

through cellophane tubing surrounded by a bath with a composition approximating normal extracellular fluid. The oncotic pressure of plasma proteins is balanced by adding glucose to the bath. With certain models, fluid can be removed from the blood by ultrafiltration. Artificial dialysis may also be used to remove exogenous toxins such as barbiturates, bromide, and salicylates. Indeed, a portion of the clinical improvement following dialysis in some patients with uremia may be related to removal of sedatives. The use of the artificial kidney requires a trained and experienced team; if this is not available, attempts at dialysis may do more harm than good.

The prime indication for artificial dialysis in acute renal failure is uncontrollable hyperpotassemia. Dialysis is also helpful, however, in temporarily inducing a return of appetite and mental clearing in severely azotemic patients whose serum potassium is normal; it may thus make management during the remainder of the oliguric period considerably simpler by preventing or delaying clinical deterioration. The electroencephalogram may improve even though serum electrolytes are not greatly changed. Acidosis cannot be successfully treated by measures short of dialysis without administering sodium; mounting acidosis in the presence of congestive heart failure is therefore another clear indication for dialysis. Sudden lowering of the serum potassium by dialysis may induce dangerous arrhythmias in digitalized patients. It should be emphasized that, in civilian practice, dialysis is seldom necessary if proper care is instituted from the onset of anuria. Extensive wounds, severe infection, or extremely prolonged oliguria may, of course, result in the accumulation of such quantities of potassium and other metabolites that conservative measures fail.

During the *early diuretic* phase, every effort should be made to avoid salt depletion and dehydration and to sustain diuresis by replacing the previous day's urinary losses. Daily weights and determinations of serum and urinary electrolytes serve as guides; a useful approximation for replacement is to give one-quarter of the urine volume as 0.9 per cent saline, one-quarter as $\frac{1}{2}$ M sodium lactate, and one-half as 5 per cent glucose in water in addition to replacing other losses. Equivalent quantities of sodium and water may be provided by mouth if oral feedings are tolerated. As azotemia recedes, tubular ability to reabsorb salt and water improves, and the daily provision of large volumes of fluid becomes unnecessary. In a patient who is alert, spontaneous intake of food and water may usually be trusted to prevent depletion after the blood urea nitrogen has fallen below about 80 mg per 100 ml. At this time protein may be allowed

ing diuresis. Urinary osmolarity is not appreciably higher than that of plasma after the first few hours of acute tubular necrosis, whereas it may be elevated in simple dehydration and other prerenal causes of oliguria. The sodium concentration of the urine in acute tubular necrosis is usually over 30 mEq per liter; in oliguria secondary to acute glomerulonephritis or renal arterial occlusion it is usually much less than this. Low urinary sodium concentrations may, however, be observed in tubular necrosis associated with terminal hepatic and cardiac failure. Failure of blood urea to rise in a stepwise fashion makes the diagnosis of tubular necrosis unlikely, even though oliguria is present. If doubt persists, a liter of glucose in water may be infused rapidly to determine the effect upon urine flow.

Lower urinary tract obstruction must always be kept in mind. A plain x-ray of the abdomen should be obtained in all patients with acute renal failure to delineate the size of the kidneys and detect radiopaque stones. If the possibility of ureteral obstruction exists, gentle investigation of the patency of one ureter is indicated.

Complete anuria for more than 48 hr should suggest obstruction, bilateral renal arterial emboli or thrombosis, cortical necrosis, or acute glomerulonephritis. Atheromatous emboli to the small renal arteries sometimes produce irreversible anuria following attempts at aortic resection. Carcinomatous obstruction to the ureters and idiopathic retroperitoneal periureteral fibrosis are frequently associated with intermittent oliguria, alternating with periods of polyuria and diuresis. Occasionally, acute papillary necrosis is attended by oliguria. Uric acid crystals may obstruct both ureters temporarily in patients with leukemia or lymphoma who have received nitrogen mustards or x-ray irradiation. Similar obstruction may be caused by certain sulfonamides given to dehydrated individuals. The prolonged anuria which occasionally follows bilateral retrograde pyelography is probably a result of obstruction to the lower ureteral orifices by inflammatory edema.

Oliguria attending the terminal stage of chronic kidney disease can usually be distinguished by the history, presence of hypertension, abnormal fundi, and small size of the kidneys. During the terminal stages of hepatic failure, especially in cases complicated by hemorrhage and hypertension, a syndrome of oliguria and progressive azotemia often appears which is associated with the lesions of tubular necrosis at postmortem but differs in some respects from the course of acute tubular necrosis outlined above. The oliguria is not severe, urine flow usually exceeding 150 ml per day. Urinary osmolarity may in some instances be distinctly ele-

vated above that of plasma, and urinary sodium concentration is low. Vigorous transfusion and the use of vasopressor agents improve urinary flow only inconstantly and transiently. Although progression of the syndrome may in rare instances be halted, a typical diuretic phase does not ensue.

Treatment. Perhaps more than in any other renal disease, the course of acute renal failure is determined by the therapy the patient receives. Treatment during the initial stages of the disease must be directed toward reversing circulatory failure, which may have initiated the ischemic episode. Although overhydration predisposes to later pulmonary edema if renal failure is established, too timid replacement of blood or saline in shocked or dehydrated patients may perpetuate oliguria and permit tubular necrosis to develop. If vasoconstrictor agents are substituted for blood in hypovolemic shock, further renal damage with ischemic coagulative necrosis of cortical tubules may result.

Having restored circulatory efficiency, only current losses should be replaced. The patient should receive enough water and salt to provide for obvious extrarenal (e.g., gastrointestinal) and urinary losses and, in addition, enough water to compensate for insensible perspiration and water in expired air. Under average conditions of environmental and body temperatures, normal hydration in an adult patient can be maintained by the daily administration of about 600 ml of water in addition to other measured losses (since some water is provided from oxidized foodstuffs and tissue breakdown). Accurate daily weights provide a reliable index of fluid balance; ideally the patient should lose $\frac{1}{4}$ to $\frac{1}{2}$ lb daily as a result of consuming his own fat calories.

At least 100 to 150 Gm of carbohydrate should be given daily, to minimize protein breakdown and prevent ketosis. Its effect in this direction is enhanced if it is administered throughout the day rather than over a short period of time. There is no evidence that high-calorie mixtures containing more carbohydrate and much fat are appreciably more efficacious in reducing protein catabolism when the intake of protein is interdicted, as it must be in acute renal failure. When nausea is not present, 50 Gm lactose, 25 Gm sucrose, and 25 Gm glucose may be dissolved in the daily water requirement, flavored with a little lemon and served cold, to be sipped throughout the day. Ordinary food, especially juices, should not be given, since potassium intake is undesirable. Oral feedings should not be attempted in the presence of nausea or vomiting. Sodium lactate, accompanied by calcium, may be given in amounts of 40 to 80 mEq per day to avoid further acidosis, when the plasma CO_2 has fallen to 16 mEq per liter. Larger amounts

higher in economically underprivileged and poorly nourished segments of the population. Toxemia of pregnancy is especially frequent in patients with prior renal and vascular disease. From 35 to 50 per cent of pregnant women with preexisting hypertension can expect to have their pregnancy complicated by a toxemic episode. The incidence increases in general with the height of the diastolic blood pressure and is especially high if in previous pregnancies preeclampsia was superimposed upon chronic hypertensive vascular disease. Preceding toxemia of pregnancy appears to predispose to recurrence in 30 to 60 per cent of patients even if blood pressure and urine have been normal between pregnancies. Evidence of pyelonephritis is encountered clinically in about one-fifth of patients with preeclampsia. Patients with diabetes are not especially susceptible to the disorder unless vascular or renal disease is present.

The onset may be either insidious or shockingly abrupt. Although toxemia commonly appears after the twenty-fourth week of gestation and frequently only a day or two before delivery, the onset may be earlier, particularly in patients with underlying renal disease. Hypertension is usually an early sign. Because of the normal decline in blood pressure during the latter two-thirds of pregnancy, the physician should not ignore the significance of a rising blood pressure, even though it may not exceed 140/90. With hypertension, headaches and visual disturbances are frequent but not universal complaints. The fundi often show narrowing and spasm of the retinal arterioles. The retina may appear glistening or wet, but the author has not been impressed with the frequency or specificity of this sign. Exudates and hemorrhage are late occurrences in severe cases.

The appearance of proteinuria is usually coincident with hypertension, although it may follow (less often, precede) the rise in blood pressure by a week or so. The amounts may vary from a trace of protein to 8 or 10 Gm in 24 hr. Granular and hyaline casts are found in the urinary sediment. Unlike acute glomerulonephritis, red cells are usually not present in large numbers. Renal concentrating ability is generally unimpaired, and phenolsulfonphthalein excretion is normal except in severe cases and in patients with previously decreased renal function. The blood urea nitrogen does not often rise above 20 mg per 100 ml. Nevertheless, glomerular filtration rate is probably diminished by the disease in most cases. Even slight nitrogen retention must be interpreted with due regard to the physiologic increase in glomerular filtration rate and fall in blood urea which characterize the normal pregnancy. Blood uric acid is commonly though not invariably elevated, reflecting a decrease in renal clearance of urate. In fulminant

cases, oliguria may be prominent and presage the acute renal failure of tubular necrosis.

The edema which characterizes preeclampsia resembles that of acute glomerulonephritis in its distribution and probably in its pathogenesis. Edema may be absent when the toxemia has been explosive in its onset, as with convulsions. In other cases excessive weight gain with puffiness of the face, fingers, and ankles is the earliest symptom, antedating hypertension or proteinuria. Edema is usually contributed to by hypoalbuminemia; yet the serum albumin, though diminished, is not often below 2 Gm per 100 ml, and the edema of toxemia is not so dramatically relieved by injecting serum albumin as is the edema of nephrosis.

Signs of cardiac failure are present in a significant proportion of cases. With the appearance of edema, orthopnea and exertional dyspnea are often exaggerated. These symptoms frequently subside with bed rest, digitalis, and diuresis. As in glomerulonephritis, the circulation time may be normal while the venous pressure is elevated.

Certain patients with severe toxemia, with or without eclamptic convulsions, may develop multiple clotting deficiencies or intravascular hemolysis, often following delivery.

Convulsions are often preceded by the development of hyperactive tendon reflexes and occasionally by epigastric pain. Though they are often associated with marked hypertension, their appearance is not necessarily correlated with the height of the blood pressure. They may occur within the first day or two following delivery, as well as before or during labor. Petechial hemorrhages are observed in the brain in most patients who die of eclampsia.

Termination of the pregnancy is usually followed by prompt improvement of the mother. Proteinuria and hypertension usually disappear by the end of 1 or 2 weeks, though occasionally they persist longer. Nevertheless, in perhaps 50 per cent of patients with preeclampsia, hypertensive vascular disease indistinguishable from essential hypertension develops later. The incidence of irreversible renal changes and of late hypertension increases significantly with the duration of the toxemia.

Treatment. The most effective treatment is prompt emptying of the uterus. Ganglionic blocking agents should not be used to treat the hypertension since they cross the placental barrier and may injure the fetus. Abrupt and severe hypotension induced by drugs may result in fetal distress and cause acute renal failure in the mother. In mild cases, hypertension may be treated by vasodilating agents like reserpine, hydralazine, veratrum, or magnesium sulfate, and edema can be eliminated with diuretics, bed rest, and a low-salt diet. When proteinuria and hypertension persist, however, it

in the diet and will generally be well utilized in replenishing tissue stores.

Prevention. The development of toxic or ischemic tubular necrosis in experimental and clinical situations is conditioned by the state of hydration and the concentration of the urine. Renal vasoconstriction is potentiated in dehydrated animals. Hemorrhagic or tourniquet shock is enhanced by dehydration and modified by prior infusions of saline. It would seem wise to give enough saline and glucose solution before and during surgical operations to compensate for antecedent losses as well as those anticipated during the operative procedure. Since dehydration contributes to the production of shock, it is likely that these simple measures will reduce the necessity for transfusions and therefore the likelihood of transfusion reactions.

Prognosis. Despite the fact that in most cases the damage to tubular epithelium is theoretically repairable, acute tubular necrosis is a dangerous disease with a serious prognosis. The mortality in many large series of cases is about 50 per cent, in spite of the most careful attention to details of fluid and electrolyte balance and with the aid of the artificial kidney. The result depends to a large extent upon the background of associated illness leading up to the acute episode and the outcome of infections acquired during its course.

When renal ischemia is extremely intense or prolonged, *acute cortical necrosis*, with destruction of glomeruli, may occur. Such lesions are not reversible and most patients die without emerging from anuria. Most instances of acute cortical necrosis have followed complications of pregnancy, particularly premature separation of the placenta, eclampsia, and septic abortion, although the disease is also encountered following severe shock in nonpregnant patients with preexisting vascular disease. Anuria for several days is common, followed by prolonged oliguria. The protein content of the urine is elevated. In the few patients who survive, renal calcification and contraction of the kidneys may be observed. The author has seen malignant hypertension develop after 4 months in one such patient.

PAPILLARY NECROSIS

When severe infection of the renal pyramids is present in association with vascular diseases of the kidney or urinary tract obstruction, *renal papillary necrosis* is likely to result. Patients with diabetes and vascular disease seem peculiarly susceptible to this complication. Pain in the flank or abdomen, chills, and fever are the most common presenting symptoms. Acute renal failure with oliguria or anuria is not infrequent. Rarely, sloughing of a pyramid may take place without symptoms in a patient with chronic urinary infection, and the

diagnosis is made when the tissue is passed in the urine or identified on pyelography. If renal function deteriorates suddenly in a diabetic patient, this diagnosis should be entertained, even in the absence of fever or pain.

PREECLAMPSIA AND ECLAMPSIA—TOXEMIAS OF PREGNANCY

The term *toxemia of pregnancy* is generally defined as including those disorders encountered during gestation or shortly after delivery, which are characterized by the appearance of hypertension, edema, and proteinuria (preeclampsia) and, in severe cases, convulsions and coma (eclampsia). There is no reason to believe that patients with convulsions suffer from a disease essentially different from that of patients with preeclampsia. Such a classification necessarily includes a large number of diverse diseases of the kidneys and blood vessels which may begin or be exacerbated during pregnancy and to which pregnancy may lend a distinctive coloration. There appears to be in addition, however, a specific disease affecting the kidneys and the vascular system, usually commencing in the last trimester of pregnancy, which in most cases is dramatically improved when the pregnancy is terminated.

Pathology. The most common histologic finding in the kidneys in toxemia of pregnancy is marked swelling of the endothelial and epithelial cells of the glomeruli. In severe or prolonged cases, thickening of afferent arterioles may be apparent. Generalized and focal thickening of the glomerular basement membrane and fibrinoid necrosis of glomerular tufts have been described at post-mortem, but these changes are rarer in renal biopsies obtained from patients who recover. Tubular necrosis is present in almost all patients who die of acute toxemia of pregnancy. Necrosis of liver cells and hemorrhages in the periportal areas are present in some but not all fatal cases; it has been suggested that these as well as the necrotic lesions of the kidneys may be secondary to vascular spasm and shock.

Clinical Features. Toxemia occurs more often in women pregnant for the first time and in those in the age group over thirty-five. It is more common with twins than in single pregnancies. Interestingly, its incidence is especially high in mothers bearing hydatiform moles, in which albuminuria and hypertension characteristically appear early rather than late in pregnancy, suggesting that the disorder is associated with the placenta, rather than the fetus. As with most vascular disorders, its manifestations are more frequent and pronounced in the obese, though paradoxically its incidence is

veins with upward blood flow, unexplained edema of the legs or lower trunk, or recurrent pulmonary emboli may suggest the diagnosis which can be established by venography of the inferior vena cava.

RENAL DISEASE IN LUPUS ERYTHEMATOSUS

Incidence. In about two-thirds of all patients with lupus erythematosus there is clinical evidence of renal involvement. Nephritis is found at post-mortem in 75 per cent of these patients, the majority of whom die of renal failure. The diagnosis of lupus nephritis was made in one-third of all adult and adolescent women with the nephrotic syndrome examined at the Presbyterian Hospital of New York over the course of 20 years.

Pathology. The earliest lesion is a focal membranous glomerulonephritis involving the periphery of the glomerular tuft, usually in conjunction with small areas of endothelial proliferation. As the disease advances, the glomerular process becomes more generalized, with diffuse thickening of the basement membrane, resulting in "wire loop" formation and intense focal cellular proliferation, with capsular adhesions and epithelial crescent formation, progressing to hyalinization. Lesions are frequently seen in various stages of development. It should be emphasized that they overlap morphologically with those observed in chronic glomerulonephritis (p. 1483). Some of the morphologic differences may be expressions of the relatively rapid rate of progression of the disease. Thus, contracted kidneys with many fibrotic and hyalinized glomeruli are uncommon, while focal zones of necrosis in the glomeruli, with nuclear fragmentation, are frequent. Hematoxylin bodies, consisting of depolymerized ribonucleic acid, are occasionally observed in the glomeruli; they have not been reported in chronic glomerulonephritis.

Clinical Features. Lupus nephritis may present as acute glomerulonephritis, "latent" nephritis with asymptomatic albuminuria, nephrosis, or chronic glomerulonephritis with renal insufficiency. Its course may be fulminating, with death in uremia after only a few weeks of onset, or the patient may live for years, with proteinuria and microscopic hematuria regarded as merely subsidiary to the other vicissitudes of the disease. In its early phases, signs of renal disease may be remittent, but when massive proteinuria or azotemia has appeared, the course is generally rapidly downhill within 1 to 3 years. Hypertension is rare unless azotemia is present or the patient is being treated with steroids. The urinary sediment is characteristic of chronic active glomerulonephritis, with leukocytes, red cell casts, doubly refractile lipid granules, and broad granular casts. Other systemic signs of lupus, such

as rash and arthritis, as well as the LE test, may disappear while the nephritis is active; this is especially likely with the development of the nephrotic syndrome or signs of uremia.

Treatment. Treatment with relatively small doses of adrenal steroids (e.g., 100 mg of cortisone daily), which may be enough to suppress fever and arthritis, rarely improves advanced lupus nephritis and does not prevent its development, though mild proteinuria and hematuria may show improvement. Larger doses of steroids (e.g., 60 to 80 mg of prednisone daily) plus antimalarials may produce temporary remission of proteinuria and improvement in renal function. Many patients, however, continue to progress regardless of treatment. This is especially true after azotemia and hypertension have appeared. Remission has been reported in some after treatment with nitrogen mustard.

SCLERODERMA

About one-third of patients with scleroderma die of renal failure, and in two-thirds renal changes are present at death. The characteristic lesions consist of extensive intimal thickening of the interlobular arteries, fibrinoid necrosis of the cortical arterioles, thickening of glomerular loops, and spotty ischemic cortical necrosis. These changes may be indistinguishable from those seen in malignant hypertension. Proteinuria does not generally exceed 2 Gm per day. The blood pressure is usually elevated, especially terminally. In exceptional instances, however, it may be normal, even in patients with widespread arterial and arteriolar lesions at post-mortem. Minimal proteinuria may be the only sign for long periods. Once renal involvement is moderately advanced, the course is rapid, leading to death from renal insufficiency a few weeks or months after azotemia has appeared. Terminal oliguria or anuria is common. The rapid progression of renal insufficiency frequently appears to be precipitated by the use of hypotensive agents. Adrenal steroids do not prevent or ameliorate the renal disease; it has been suggested that they accelerate it, but the evidence for this is not entirely convincing.

PERIARTERITIS NODOSA— HYPERSENSITIVITY ANGIITIS

The kidney is said to be involved in approximately 80 per cent of all patients with periarteritis nodosa. It must be pointed out that precise nosology in this area is somewhat complicated by the fact that arteritic lesions may occur in the course of malignant hypertension and may occasionally appear in the course of glomerulonephritis.

is doubtful that such treatment prevents further vascular injury to the placenta and the kidneys. In such instances attempts to prolong the pregnancy for several weeks are associated with a high fetal mortality and the risk for the mother of permanent vascular disease.

ORTHOSTATIC AND FUNCTIONAL PROTEINURIA

In perhaps three-quarters of adolescents and young adults, proteinuria may be induced by prolonged standing in the erect position. This effect is more pronounced when a lordotic posture is assumed. In some patients lordosis has been demonstrated to result in compression of the inferior vena cava by the liver, and it has been postulated that the resulting increase in pressure in the renal veins is responsible for proteinuria. It appears more likely, however, that changes in the renal circulation secondary to peripheral sequestration of blood may be involved since proteinuria can be produced in susceptible individuals by applying tourniquets in the supine position, prevented by standing upright in water, and aggravated by the peripheral vasodilatation induced by heat. Urine passed early in the morning, before arising, is free of protein although of high specific gravity. Care must be taken to have the patient empty his bladder at midnight, without getting up, so that urine formed in the erect position during the previous evening is discarded. Urine produced after the patient has been up may contain as much as 1 to 3 Gm of protein per liter, although usually less than 1 Gm of protein is excreted per day. The excretion of casts and other formed elements may also increase with the appearance of protein. Often a history of easy flushing, fainting, or other evidence of autonomic instability is obtained. It should be recalled that the erect posture may increase proteinuria in some patients with renal disease, especially in healing or "latent" nephritis. Such cases, however, make up only a small percentage of young individuals with orthostatic proteinuria, in the majority of whom the condition is entirely benign and unassociated with other clinical evidence of impaired renal function.

Strenuous physical exercise produces transient proteinuria and microscopic hematuria in most people. "Functional" proteinuria may also occur during fever, after injections of epinephrine or norepinephrine, and during severe mental or emotional stress.

RENAL ARTERIAL OCCLUSION

Arterial infarction of the kidney is usually attended by sudden sharp unremitting pain in the upper abdomen or flank. The most common cause

is embolic occlusion. Fever and moderate leukocytosis are common, especially when a major branch of the renal artery has been occluded. Gross hematuria is not unusual, and microscopic hematuria is present in more than half the cases. The blood urea nitrogen usually is not abnormal unless there is contralateral disease. Shortly after a renal infarct, the kidney may not function on intravenous pyelography, although it appears normal in size and retrograde pyelograms are normal. During the ensuing days or weeks, function is slowly regained.

When occlusion of the renal artery is incomplete as a result of atherosclerotic narrowing, or if a branch of the main renal artery is occluded, and viability of kidney tissue is preserved by collateral circulation, hypertension may ensue, which is often of the rapidly progressive type, though reversible by nephrectomy. In such patients intravenous pyelograms may be normal. Often the affected kidney is contracted. In a significant minority of cases, albuminuria is absent and the urinary sediment may be completely normal. The diagnosis may be made by studies of the volume and composition of urine obtained on bilateral ureteral catheterization and by aortography (p. 1352).

RENAL VEIN THROMBOSIS

Etiology. One or both kidneys may be involved by renal vein thrombosis. Occlusion of renal veins usually implies thrombosis of the inferior vena cava as well. A common cause is invasion of the veins by hypernephroma or compression by malignant metastases to retroperitoneal lymph nodes at the level of the celiac axis. Thrombophlebitis of the legs with extension upward, periarthritis, congestive heart failure, or severe dehydration, especially in children, may be etiologic factors. The venous occlusion may follow an abdominal injury or operation. In adults, renal vein thrombosis may occur as a secondary and often terminal complication of renal disease which has previously caused perinephric inflammation or reduction of renal blood flow. It is particularly likely to occur in papillary necrosis and in renal amyloidosis.

Clinical Features. Sudden complete thrombosis of a renal vein causes severe lumbar pain, enlargement of the affected kidney, hematuria, and proteinuria. If the condition is bilateral, oliguria and death from uremia usually ensue. If the occlusion is more gradual, renal function may be partially preserved by the development of collateral venous channels. In a few such cases, massive proteinuria results in a full-blown nephrotic syndrome; in other instances, proteinuria is not prominent and is overshadowed by hematuria. The blood pressure is usually normal, and when hypertension occurs it is not severe. The presence of collateral abdominal

ment of renal function is not necessarily correlated, however, with the *degree* of albuminuria or Bence Jones proteinuria. In addition, hypercalcemia may produce transient or irreversible renal damage. In some cases the kidney may be infiltrated by amyloid. Rarely, deposits of myeloma cells may diffusely infiltrate the kidneys.

The major early change produced by the Bence Jones proteins is in the tubules. Proximal tubular cells are swollen and have droplet or rodlike inclusions. Large obstructing casts form along the entire length of the renal tubule, most prominently in the straight tubules of the medulla. These are often laminated and surrounded by multinucleated giant cells possibly derived from degenerating tubular epithelium. In addition, there is usually distinct thickening of the glomerular basement membrane, without cellular proliferation or crescent formation. Vascular sclerosis is not common; when it occurs it is probably coincidental.

Alteration in renal function is most frequently characterized by nitrogen retention and loss of concentrating power, without hypertension, retinitis, or edema. Proteinuria is usually present, consisting of albumin as well as certain globulins and Bence Jones proteins which may be excreted only intermittently. Anemia may seem out of proportion to the degree of azotemia. The disease may superficially resemble the chronic forms of glomerulonephritis or pyelonephritis. The nephrotic syndrome probably does not occur in multiple myeloma unless the disease is complicated by amyloidosis. In unusual instances, and before azotemia has become prominent, disturbances in renal tubular function may dominate the picture, with renal glycosuria, aminoaciduria, low levels of serum uric acid, and renal potassium wasting. Loss of concentrating power is common, and nephrogenic diabetes insipidus has been reported. Renal loss of phosphate with consequent hypophosphatemia and elevation of the serum alkaline phosphatase may, in rare cases, cause confusion with hyperparathyroidism. Because of the exceptional tendency to formation of obstructive casts, procedures which cause dehydration must be carefully avoided in the patient with multiple myeloma. Acute anuria has been observed in several instances following intravenous pyelography, probably as a result of the dehydration which is often induced in preparing for this procedure. Acute renal failure with anuria or oliguria which follows an episode of dehydration in an elderly person should suggest the possibility of myeloma kidney.

HYPERCALCEMIC NEPHROPATHY

Acute elevations of serum calcium may be associated with marked polyuria, succeeded by dehy-

dration, oliguria, and rapidly advancing azotemia. Prolonged hypercalcemia and/or hypercalcuria, as in hyperparathyroidism, vitamin D intoxication, the milk-alkali syndrome, Boeck's sarcoid, multiple myeloma, or carcinomatosis, may result in diffuse nephrocalcinosis and present as renal insufficiency, insidious in onset and only slowly progressive. In such cases, severe disturbances in renal function need not be associated with stones or with radiologic evidence of calcification in the kidneys. Impairment of urinary concentrating capacity is an early sign of calcium nephropathy, and polyuria and polydipsia are frequent, although not invariable. In more severe cases, there is a depression in filtration rate and renal blood flow, with retention of nitrogen. The urinary sediment may contain red blood cells, as well as leukocytes and white blood cell casts; in many patients, however, it is remarkably free of formed elements. Unless congestive heart failure is present, proteinuria is slight. Hypertension is common when nephrocalcinosis is established and does not disappear when the serum calcium has returned to normal, even though renal function improves. Renal insufficiency may sometimes be completely or partially reversed when hypercalcemia is eliminated. In other cases, uremia and hypertensive vascular disease progress to a fatal termination despite the disappearance of hypercalcemia. The degree of reversibility of renal impairment is related to the extent of scar formation and permanent medullary obstruction by calcium precipitates as well as to the presence of vascular disease and infection.

POLYCYSTIC KIDNEYS

In this disorder normal renal tissue is gradually replaced and encroached upon by multiple cysts of the renal parenchyma of varying size. The disease is congenital and in one-half to two-thirds of cases appears to be familial and transmitted as a dominant gene, which is probably not sex-linked, since the incidence is equal in the two sexes. The condition is bilateral, though one kidney may be involved to a greater extent than the other.

Pathology. The kidneys are enlarged to several times normal size and are filled with grapelike clusters of cysts containing clear or hemorrhagic fluid. Between the cysts islands of normal or partially fibrotic renal parenchyma persist. In infants the cysts are said to be closed and do not communicate with the renal pelvis, while in adults there is evidence that some cysts are functional. In patients with polycystic kidneys cysts of the liver may be present and, more rarely, cysts of the pancreas and spleen. These are usually asymptomatic. There is a high associated incidence of intracranial aneurysms, and death from cerebral hemorrhage occurs in about 10 per cent.

Pathology. Renal lesions in periarteritis are of two types. The first is characterized by segmental fibrinoid necrosis of part or all of an arterial wall, with an inflammatory perivascular infiltrate. Usually, arteries of medium size are involved (arcuate arteries or larger), but arterioles and even capillaries may be attacked. Signs of organization may be evident, with fibrous replacement of the damaged media and the formation of aneurysms at weakened spots in the larger muscular arteries. Multiple infarctions and gross cortical scars are apparent in the renal parenchyma. There may be scattered focal glomerulitis of varying age and activity. The second type of involvement is characterized by an active, rapidly progressive glomerulonephritis, with widespread fibrinoid necrosis of glomeruli and epithelial crescent formation. Combinations of these types of lesions may occur.

Clinical Features. With lesions of the larger renal arteries, hypertension is usual and may dominate the clinical picture. Albuminuria is always present, and the urinary sediment frequently contains red cell casts and fat bodies. Episodes in which the urine is grossly bloody are common. Uremia may be noted terminally, but azotemia frequently is absent or mild, and only slowly progressive. Remissions and relapses often mark the clinical course. Persistent hypertension may be a serious sequel when the disease is no longer active.

When the clinical and pathologic features of acute glomerular nephritis are present (as in the variety of hypersensitivity angitis commonly caused by reaction to drugs), hypertension is more often absent, even in the presence of marked azotemia. Although death from renal insufficiency usually takes place within 6 months to a year of onset, in milder cases permanent spontaneous remissions have been observed.

Periarteritis should be suspected in patients with renal failure or hypertension, especially when features suggesting glomerulonephritis are present, when other organ systems are involved, or in the presence of obscure fever or unexplained leukocytosis or eosinophilia.

Large doses of adrenal steroids produce improvement in renal function in some patients. In a few of these, the manifestations of renal involvement completely disappear and the remission persists after steroids are withdrawn. In others, maintenance on steroids is necessary to sustain the remission, and in many patients the renal lesion appears to progress in spite of treatment.

AMYLOID KIDNEY

Renal amyloidosis is most commonly encountered as a complication of a variety of chronic suppurative diseases, such as osteomyelitis, tuberculosis, tertiary syphilis and leprosy, as well as Hodgkin's

disease, ulcerative colitis, and rheumatoid arthritis. As the incidence of chronic infection has declined owing to the introduction of antibiotics, the amyloid kidney of "primary amyloidosis" and amyloidosis secondary to multiple myeloma and rheumatoid arthritis have become relatively more prominent. Amyloid involvement of the kidneys, as well as of other organs, commonly occurs in the course of familial Mediterranean fever, where renal insufficiency secondary to amyloidosis is usually the cause of death. The clinical and pathologic features of the renal disease produced by "primary" and "secondary" amyloidosis are similar.

Amyloid deposition may be most prominent in the walls of blood vessels (especially the small arteries), in the glomeruli, or surrounding the collecting tubules and small blood vessels of the medulla. In all these locations its distribution often tends to be patchy rather than diffuse and uniform.

The clinical picture is influenced by the location and degree of involvement. When amyloid deposits are limited to blood vessels and to occasional focal deposits in glomeruli, mild proteinuria, sometimes with hematuria, may be the only sign. On the other hand, when glomeruli are massively infiltrated, heavy proteinuria is the rule, associated with the nephrotic syndrome. In such cases, glomerular filtration may be surprisingly well maintained despite extensive deposits of amyloid in the malpighian tufts. The rare instance of amyloidosis confined chiefly to the medulla may be marked by polyuria resistant to vasopressin. Hypertension is unusual unless the disorder has progressed to the stage of azotemia and contracted kidneys. Generalized muscular weakness, difficulty in swallowing, and postural hypotension are frequent accompaniments of primary amyloidosis. Biopsy of the liver or kidney is useful in establishing the diagnosis. The course of the disease is generally prolonged, but in some cases secondary to advanced tuberculosis, only 6 months may elapse from the first appearance of albuminuria to the development of advanced uremia. Death occurs from the primary disease, amyloid involvement of the myocardium, intercurrent infection, or renal insufficiency. The disease does not respond to steroid treatment. In those instances in which a chronic suppurative disease can be eradicated, a complete remission may be observed.

MULTIPLE MYELOMA

Impairment of renal function occurs in over 50 per cent of patients with multiple myeloma. Proteinuria is even more common. Renal damage can be related in many cases to the excretion of abnormal proteins of low molecular weight and the injurious effect of these substances on the renal tubules and ultimately the entire nephron. Impair-

havior problem, while the kidneys are irretrievably damaged.

THE KIDNEY OF GOUT

From 30 to 50 per cent of gouty patients are said to die of renal disease. The kidney of most patients with gout contains characteristic fan-shaped clefts containing deposits of urate in the interstices of the medulla. Pyelonephritis is a frequent finding, and arteriolar sclerosis is almost always present.

Urate calculi occur in approximately 15 per cent of patients with gout and are particularly common during uricosuric therapy if a high fluid intake is not maintained. Both uric acid stones and interstitial deposits of urate crystals in the kidney may occur in patients with hyperuricemia who have never had gouty arthritis.

The most common indications of early renal damage are mild proteinuria, decreased excretion of phenolsulfonphthalein, and a reduction in concentrating ability. Slowly progressive azotemia with minimal albuminuria and little or no abnormality in the urinary sediment may characterize the course of some patients. Though hypertension may be absent, the blood pressure is commonly elevated; in fact, it has been suggested that hypertension and vascular sclerosis, especially nephrosclerosis, occur as part of a constitutional diathesis of which gout or hyperuricemia is a component part. Hyperuricemia and evidence on renal biopsy of arteriolar sclerosis may occasionally be the only positive findings in patients with asymptomatic proteinuria.

In rare instances of gouty kidney, renal function has been reported to improve slowly and urate stones to dissolve following the long-term administration of a high fluid intake and alkali, in association with uricosuric agents.

NEPHROLITHIASIS

Renal stones may vary in size from tiny particles to large staghorn calculi which fill the entire renal pelvis. They may be asymptomatic or may continue to be formed and passed for years with no deleterious effect on renal function and no discomfort except occasional renal colic. Even a large staghorn calculus may produce no symptoms save, perhaps, for occasional nagging abdominal or flank pain. Often, however, renal calculi are associated with infection and progressive encroachment on renal function. Stones passed from above are rarely retained in the bladder unless there is obstruction and residual urine.

The typical attack of renal colic is exquisitely painful, causing the patient to double up in agony. The crampy pain begins in the side or back, radiat-

ing to the lower abdomen, genitals, and inner thigh. The attack usually persists for several hours, although it may be over in a matter of minutes. Dysuria is frequently present, and even after the attack has subsided, tenderness along the course of the ureter often persists. Fever and leukocytosis signal the presence of associated infection. Hematuria and proteinuria are almost always present. Sometimes the pain is not referred in the usual manner and may simulate gallbladder disease, appendicitis, peptic ulcer, or disease of the spine. Renal colic may also be produced by blood clots or pus obstructing the ureter.

In about half of all patients with renal calculi, some predisposing causes can be found. These include hyperparathyroidism, excessive ingestion of milk, alkali, and vitamin D, bone disease producing hypercalcaemia, sarcoid and renal tubular acidosis. Idiopathic hypercalcaemia is found in a large proportion of patients with recurrent calcium stones.

Cystinuria (p. 747) is a congenital disorder characterized by decreased tubular reabsorption of cystine, arginine, ornithine, and lysine. Owing to its relative insolubility, cystine tends to precipitate in the urinary tract to form stones which are radiopaque on account of their high content of sulfur. The condition may be diagnosed from the hexagonal appearance of cystine crystals in the urine and their characteristic reaction with nitroprusside. Cystine stones may be dissolved or prevented from forming if the reaction of the urine is kept alkaline and the urine volume high. Hereditary glycinuria is a rare familial disorder associated with nephrolithiasis and excessive urinary excretion of glycine unaccompanied by other amino acids.

Uric acid stones are radiolucent, form most readily in acid urine, and may be prevented if the urine is kept persistently alkaline. They frequently complicate gout and may appear in a variety of hematologic diseases, notably polycythemia. More than half of all patients with urate calculi have neither hyperuricemia nor increased urinary excretion of uric acid. In this group of patients an unexplained tendency to excrete urine of pH below 5.5 may predispose to uric acid stones.

Although most patients with calcium oxalate stones do not excrete excessive amounts of oxalate, the rare condition of primary hyperoxaluria is characterized by progressive calcium oxalate urolithiasis and nephrocalcinosis beginning in early childhood. Finally, primary renal infection, especially with urea-splitting organisms and in the presence of hydronephrosis, may promote the formation of renal calculi.

Treatment must be individualized and governed by the patient's symptoms and the signs of associated renal disease. A small asymptomatic calculus

Clinical Features. The disease is found in infants, many of whom are premature and in whom it is rapidly fatal, as well as in adults in whom the course is only slowly progressive. The two diseases appear to be distinct, since families have not been reported in which both the infantile and the adult forms have appeared. The condition in the adult is commonly discovered in the fourth, fifth, and sixth decades, frequently in the course of a routine physical examination or as part of an investigation of asymptomatic hematuria, proteinuria, or hypertension. Both kidneys are usually palpable; only one can be felt in one-fifth of the cases, and occasionally no mass can be palpated. In all instances, however, intravenous or retrograde pyelography demonstrates enlarged kidneys with elongation of the pelvis, flattening of the calyces, and indentations due to the cysts. Lumbar and abdominal ache is a frequent complaint, owing to the weight of the kidney which produces tension on the pedicle, to intracystic hemorrhages, or to pressure on other organs. The pain is often increased by exertion and relieved by lying down. Pain may also be colicky and associated with hematuria and the passage of clots or with concomitant renal calculi. Hypertension appears in the third or fourth decade, when symptoms referable to high blood pressure may predominate. After the age of forty or forty-five, the more common presenting complaints are those associated with renal insufficiency. When a patient presents with uremia and a palpable "liver" and "spleen," the diagnosis of polycystic kidneys must be considered. Polyuria is common and oliguria rare, even terminally. The average age at death is between fifty and sixty years; several patients have lived past seventy. Although the rate of progression may be extremely slow, patients generally do not live longer than 5 years after the blood urea nitrogen rises above 50 mg per 100 ml; superimposed pyelonephritis, however, occurs frequently and may induce renal decompensation which can be reversed by appropriate treatment.

Treatment. It is important to remember that polycystic kidney disease is compatible with a normal life span. Puncture or marsupialization of the cysts has not been demonstrated to prolong life and may introduce a disastrous infection. Because of the high incidence of bilateral disease, excision of one polycystic kidney is practically never indicated unless it is irretrievably infected or causing alarming hemorrhage, and then only after the other kidney has been shown to have fair function and to be only moderately involved in the cystic process. Hematuria usually responds to bed rest but should be disregarded if it is microscopic and asymptomatic. Pregnancy may be undertaken before hypertension and azotemia have appeared.

OTHER CYSTS OF THE KIDNEY

Solitary cysts usually occur at the lower pole, projecting from the surface of the kidney. They contain a serous fluid which is not urine. They may be associated with a dull, dragging pain in the side, but are most often asymptomatic unless complicated by hemorrhage of infection. Occasionally one kidney is completely replaced by *multiple congenital cysts*, while the other is uninvolved. *Multiple small retention cysts*, secondary to obstruction of tubules, are common in nephrosclerosis and pyelonephritis. *Medullary cystic disease* is a rare disorder of childhood in which the medulla is honeycombed with small cysts of uniform size, lined with epithelium. The kidneys are not enlarged. Death occurs, sometimes after many years, from renal insufficiency. *Echinococcus cysts* occur in the kidney in a small percentage of infestations.

OTHER MALFORMATIONS

Congenital malformations of the kidney are sometimes associated with malformations of the external ear. Complete absence of one kidney occurs about once in 500 births. *Unilateral hypoplasia* is a rarer congenital anomaly. *Horseshoe kidney* results from fusion of the renal blastemas at the eighth to tenth fetal week, generally at their lower poles. The common location is close to the region of the aortic bifurcation. The anomaly is found once in every 500 to 1,000 autopsies and in most instances is asymptomatic and compatible with long life. It may, however, be complicated by renal calculi, recurrent pyelonephritis, hematuria, and abdominal pain. A few patients have nausea and vomiting associated with abdominal pain which is accentuated by hyperextension and relieved by leaning forward (Rovsing's syndrome). In some, a mass may be palpated in the lower abdomen. In *crossed ectopia* the renal blastema becomes deviated to the opposite side where it usually lies caudal to the normal kidney, with which it may fuse. Its ureter usually crosses the midline to terminate in the normal position. Such kidneys, as well as *unilaterally fused kidneys*, are predisposed to hydronephrosis and pyelonephritis, but not to other renal lesions. Pain is the most common symptom; many patients are entirely asymptomatic.

Anomalies of the ureter include bifurcation, complete reduplication, and abnormal implantation in the bladder, as well as stricture at the ureteropelvic or ureterovesical junction. Habitual reflux from the bladder into the ureter during the act of voiding may initiate hydronephrosis and infection. *Anomalies of the vesical neck* may underlie enuresis in children, which may sometimes be treated as a be-

patients with hypernephroma survive more than 10 years

Papillary neoplasms of the renal pelvis are often associated with similar tumors of the ureter and bladder. Hematuria is the outstanding symptom. An association with calculi and infection is frequent. Carcinoma of the renal pelvis may appear deceptively benign, and failure to find infiltration at operation does not ensure survival. The prognosis is worse than that with hypernephroma.

The most frequent symptom of tumors of the bladder is painless hematuria. Dysuria and frequency are also common, especially with superimposed infection. A small number of papillary bladder tumors arise from metaplasia of the epithelium of the bladder which follows long-standing cystitis. The incidence of bladder tumors is said to be increased in workers exposed to certain aniline dyes.

entrapped in a renal calyx and unassociated with infection may be best left alone. Many stones pass spontaneously, but in the majority of instances special urologic and surgical procedures are eventually required. Daily urine volume should be kept over 2,500 ml. Special emphasis should be placed on drinking before retiring and once more during the night. Infection should be vigorously treated. Aluminum hydroxide or aluminum carbonate gel in amounts of 30 ml three or four times daily has been advocated to reduce the intestinal absorption and urinary excretion of phosphate in individuals with calcium phosphate stones.

SICKLE-CELL NEPHROPATHY

Patients with sickle-cell anemia often develop progressive changes in renal function as a result of multiple small ischemic and hemorrhagic infarcts in the kidney. In children the principal anatomic finding is congestion of blood vessels with sickled erythrocytes; in adults interstitial fibrosis and areas of cortical necrosis and hyalinization may be seen. Frequently the changes resemble those of chronic glomerulonephritis. There is early impairment of renal concentrating ability, even when blood urea nitrogen, glomerular filtration rate, and renal plasma flow are normal. This selective disturbance in renal function may be present in patients with sickle-cell trait as well as in the full-blown disease. It is said to be temporarily reversed in children by transfusion of normal blood, but this is not the case in adults. Gross and microscopic hematuria occur frequently; bleeding may come from lesions in the papillae and pelvic mucosa as well as military infarctions in the cortex. Hypertension is not common. Despite the high incidence of at least minimal renal changes, the sickle-cell trait does not appear to predispose to toxemia of pregnancy.

CHYLURIA

The chief cause of chyluria is filariasis (p. 1223) with obstruction between the abdominal lymphatics and the thoracic duct, producing lymph varices in the kidney which rupture into the renal tubules. The urine is milky and on standing settles into a top layer of fatty material, a middle pinkish layer, often containing a clot, and a bottom layer containing blood and debris. Hematuria is common, and pyelonephritis is almost universal. Microfilariae are usually found in the urine for about 6 weeks after an acute infection but not thereafter unless the patient is in an endemic area. The lymph and blood may coalesce into ureteral casts, causing flank pain and renal colic. Chyluria may disappear with recumbency and be aggravated by exertion. The

condition may be entirely suppressed in some cases by wearing a tight abdominal corset.

RADIATION NEPHRITIS

Following the administration of large doses of x-ray (2,300 r during 5 weeks) to the kidneys in the course of therapy for abdominal carcinoma or lymph node metastases from testicular tumors, a characteristic syndrome may develop. The latent period between irradiation and the appearance of symptoms is usually at least 6 months but may be much longer. Hypertension invariably appears and may lead to congestive heart failure, retinopathy, and encephalopathy. Refractory anemia is often prominent. Uremia is usually progressive, but in some cases renal insufficiency may be reversible, improvement commencing about 6 months after the onset of symptoms. Proteinuria is present but slight, hematuria is characteristically absent. Oliguria is never observed except with heart failure. The clinical disease may mimic either benign or malignant hypertension or chronic glomerulonephritis. Histologic features include widespread fibrosis between atrophic tubules, damage to almost all the glomeruli, and fibrinoid necrotic lesions of arterioles.

MEDICAL ASPECTS OF RENAL TUMORS

Malignant tumors of the kidney occur chiefly in childhood and after forty. The incidence is considerably higher in males. The common malignant tumor of children is *Wilms's tumor*, or embryonal adenocarcinoma, which constitutes 20 to 25 per cent of all malignant neoplasms of childhood and is observed before the age of seven in 90 per cent of cases. The tumor usually presents as a palpable abdominal mass and may grow to enormous size. It is the only renal neoplasm associated in a high proportion of cases with hypertension.

In adults *hypernephroma* is the most common neoplasm of the kidney. The classic triad of hematuria, flank pain, and abdominal mass is present in two-thirds of the cases, but not infrequently the first symptoms arise from metastases to lung, bone, liver, or brain. Obscure fever is a common presenting symptom, even when evidence of infection is lacking. Serum alkaline phosphatase is frequently elevated, regardless of the presence or absence of bony metastases. In rare instances, polycythemia may be observed, unaccompanied by leukocytosis, thrombocytosis, or splenomegaly. In such cases the polycythemia may be cured by removal of the tumor. Hypertension, if present, is coincidental and is not improved by nephrectomy. Extension of the tumor into the renal veins with subsequent venous thrombosis is not infrequent. About one-quarter of

with cardiac enlargement, the planographic technique may be required.

Even more frequent are the unexpected radiologic changes in the lungs. Large irregular shadows are often caused by the various pneumonias, by tuberculous and fungous infections, by tumors, and by numerous other disorders. Some of the more important causes of discrete localized lesions are listed in the following table.

Simple Procedures. Acute bronchitis and acute pleuritis, the two most frequent disorders of the lower respiratory tract, cause no changes in the

x-ray but are readily detected by the history and the physical examination. However, there are many disorders of the pulmonary parenchyma which produce radiologic changes prior to physical signs. Therefore, an x-ray film of the chest is to be routinely made in patients with pulmonary problems. When the dynamic functions of the thorax and lungs are involved, as in patients with emphysema or with diaphragmatic paralysis, fluoroscopy is useful, provided the undesirability of excessive radiation is remembered.

The total vital capacity is a valuable guide to

Section 4: The Respiratory System

INTRODUCTION

*Ben V. Branscomb and
T. R. Harrison*

The distortions of function responsible for the manifestations of pulmonary disorders have been considered in a preceding section (p. 104). Here, we are concerned with the specific diseases which involve the respiratory system.

Presenting Problems. The patient with respiratory disease may exhibit one or more of a number of problems. The most compelling of these is sudden severe dyspnea. Under such circumstances a quick tentative distinction must be made between acute failure of the left side of the heart and some pulmonary disorder such as acute pneumothorax or asthma. Only after immediate therapy has led to improvement will there be opportunity for more detailed study. When doubt exists it may be necessary to initiate procedures which are beneficial in both cardiac and pulmonary dyspnea (pp. 1383 and 1573).

Another common situation is that of fever with progressive dyspnea. Here, the differentiation of pneumonia from infarction and from other disorders will usually be apparent in young persons but may require extensive study in older individuals (p. 891).

The problem presented by the afebrile patient with slowly progressive exertional dyspnea is less urgent, and the recognition of pulmonary or cardiac disease as the cause will usually be achieved on the basis of the office examination, supplemented by observation of the response to therapeutic measures. Shortness of breath at rest is likely to be more serious and, when not obviously due to

bronchial asthma or to emotional disturbance will commonly call for an initial period of hospital management.

Even more frequent is the syndrome of cough, with little or no dyspnea or fever but often associated with difficulty in producing sputum. Since the usual cause is acute bronchitis, with recovery in a short time, a watch-and-wait period of ambulatory treatment is justified. Persistence of the symptoms should raise the question of tuberculosis or carcinoma and call for more complete investigation.

Hemoptysis, unless minimal and obviously due to the strain of coughing, should be regarded as serious and as an indication for detailed study (p. 122).

Various combinations of these presenting syndromes are often encountered. Only by the exercise of sound judgment, based on a comprehension of all the likely causes, will it be possible to avoid the error of overlooking grave disorders in their earlier stages and the opposite mistake of subjecting every patient with minor symptoms to unnecessarily elaborate and expensive investigation.

Another common presenting problem is that of the patient who has minimal or no symptoms but is found in the course of a routine x-ray of the chest to display some unexpected change. This may involve either the lungs or some other thoracic structure. Thus notching of the ribs may furnish the first clue to coarctation of the aorta, while a cervical rib may explain an otherwise mysterious paresthesia of the arm. Similarly, the finding of an unusual shape or of enlargement of the heart may be the initial guide to the presence of a curable congenital or acquired disorder. In order to avoid the common error of confusing an apical fat pad

II. Physiologic

- | | |
|--------------------------------|--|
| A. Disturbances of ventilation | } In most instances there are various combinations of these physiologic disorders. |
| 1. Restrictive | |
| 2. Obstructive | |
| B. Disturbances of diffusion | |
| C. Disturbances of perfusion | |

III. Clinical classification of chronic nonspecific lung disease and of complicating cor pulmonale

- A. Bronchial asthma (see Chap. 232)
- B. Bronchitis (including the milder type and the grave variety associated with destruction of bronchioles, the latter being usually consequent to the former)
- C. Emphysema
 1. Relatively innocent varieties (including compensatory, senile blebs without generalized obstruction, etc.)
 2. Generalized obstructive (essentially the same as advanced chronic bronchitis with bronchiolar destruction)
- D. Cor pulmonale in chronic nonspecific lung disease
 1. Right ventricular hypertrophy without failure
 2. Right ventricular hypertrophy with failure

It should be noted that the term "generalized obstructive lung disease" includes both a reversible condition (bronchial asthma) and the largely irreversible disorder generalized obstructive emphysema, which with the associated bronchitis may be designated as "chronic diffuse nonspecific lung disease."

In the following presentation, the etiologic classification will be used for those disorders which fall into clearly defined categories. However, the clinical and physiologic classifications will be employed in the discussion of chronic bronchitis, of emphysema, and of the large group of diseases which restrict ventilation and impair diffusion.

Arrangement of Chapters. Acute disorders of the respiratory tract are usually of infectious nature, and most of them have been discussed in preceding chapters dealing with illness due to specific organisms. This section of the book is, therefore, concerned mainly with chronic diseases.

Because of the importance of chronic obstructive disease (bronchitis and emphysema), this is discussed first. Then the restrictive and diffusional disorders are considered, followed by various specific conditions.

Those therapeutic procedures which are of limited scope and mainly applicable to a specific disease are considered with that disease. Those which have a wider application are placed in the last chapter, which deals with the more general treatment of pulmonary problems.

259 DISORDERS OF THE UPPER RESPIRATORY TRACT

Ivan L. Bennett, Jr.

This chapter summarizes some of the diseases that are manifested in whole or in part by structural alterations or dysfunction of the nose, nasopharynx, paranasal sinuses, and larynx. In the course of their normal function of warming, humidifying, and preliminary cleansing (by impingement of inhaled particles upon the mucosa) of inspired air, these passages are exposed to a multitude of irritants and infectious agents. Their lining membranes contain many mucous glands and deposits of lymphoid tissue; the vascular bed of the nasal mucosa is capable of such rapid and extensive alterations in response to local or systemic stimuli that it is often classified as an erectile tissue. Engorgement, hypersecretion of mucus, and hyperplasia of the adenoids and other lymphatic foci in response to irritation or infection can produce acute or chronic obstruction of the passages draining the sinuses, conjunctivas, and middle ears. This leads to initiation or aggravation of bacterial infection in these areas.

The annoying and distracting discomfort occasioned by interference with inspiration and speech, coupled with the frequency of viral and allergic disorders of this region, makes upper respiratory disease the most important transient disability that afflicts mankind.

DISEASES OF THE NOSE AND NASOPHARYNX

Nay fever, vasomotor rhinitis, and complicating nasal polyposis are discussed on p. 1259.

Acute coryza and other forms of viral rhinitis are discussed on p. 1116; the upper respiratory prodrome of measles is discussed on p. 1158.

Among bacterial infections, the persistent rhinitis ("Snuffles") of congenital syphilis (p. 1078), nasal diphtheria (p. 987), and furunculosis of the nares (because of the complication of cavernous sinus thrombosis, p. 1046) are the more important.

Clear, watery discharge characterizes cerebrospinal rhinorrhea. Chronic, mucoid, occasionally blood-stained discharge is frequent in children with enlarged adenoids.

Unilateral purulent or sanguineous discharge suggests foreign body, diphtheria, or tumor.

Perforation of the nasal septum results most commonly from habitual nose picking, but syphilis and occupational exposure to chromate are other causes to be considered. Many diseases, some of

the presence of a restrictive disorder, and one of the simple respiratory flow tests may be essential for the early recognition of an obstructive disorder. Only occasionally will the more complex methods for study of respiratory function be needed (p. 107).

The x-ray will often be of particular importance in detecting the presence of pulmonary disease; the sputum in determining its cause. The history will usually be the most accurate guide to its rate of progress. Treatment will depend on sound clinical judgment based on the total information supplied by these multiple methods of study.

The Systematic Approach to Therapy. In order to avoid neglect of important methods of treatment, the following problems must be considered in all patients with respiratory disorders.

The importance of infection is to be evaluated. Antibiotics should usually be withheld when the evidence points toward an acute viral disorder, and their use in bacterial infections will depend in large measure on cultures and smears of the sputum.

The role of bronchial obstruction should be considered as a likely factor in aggravating either dyspnea or infection. The relative significance of allergy, of mechanical blockage by thickened sputum, and of bronchospasm must be assessed.

A search should be made for evidence of failure of the right ventricle in order that the need for digitalis, oxygen, or venesection may be determined.

In persons with chronic pulmonary disorders, the therapeutic plan will also depend on the extent to which there is reversibility of the functional impairment. This is always present in some measure, but the degree varies markedly from one patient to another.

Terminology and Classification. The important conceptual clarifications of the past few years have been accompanied by confusion in nomenclature. Thus the term "emphysema" is employed by some to mean any overdistended lung; others reserve it for that distention due to destruction of the walls of the respiratory bronchioles or alveoli. Some authors consider a change in shape of the thorax with increased anteroposterior diameter due to senile kyphosis as a variety of emphysema; other writers insist that such a designation is unjustified unless there is also clear evidence of expiratory obstruction. There is no general agreement concerning the inclusion or exclusion of the elderly person with a few radiologically demonstrable but asymptomatic bullae in the category of emphysema. These differences in usage have led some of the students of pulmonary disease to believe that the word "emphysema" should be reserved for the pathologist and that clinicians should utilize the more precise

(if more awkward) term "generalized obstructive lung disease," subdividing it according to its episodic and reversible (bronchial asthma) or persistent and largely irreversible (clinically significant emphysema) varieties.

"Chronic bronchitis" is used by some to signify a grave and progressive disorder, terminating in respiratory or cardiac failure, and by others to indicate a minor nuisance, with cough and expectoration in a vigorous individual. This is analogous to the use of the unqualified term "hypertension" to describe both the healthy person with minor elevation of systolic pressure and the patient with malignant nephrosclerosis.

In the strictest sense "bronchiectasis" means dilated bronchi, and some apply this term to any patient with persistent abundant purulent sputum dependent on diffuse bronchial disease (cylindrical bronchiectasis). Other writers decry the word "bronchiectasis" for the disorder which they designate as "chronic bronchitis," and would limit it to the localized saccular type which is sometimes amenable to surgical treatment. The evidence of the postmortem examination suggests that neither term (bronchitis nor diffuse bronchiectasis) is ideal because, although both conditions are present, it is the destructive bronchiolitis which is responsible for the expiratory obstruction and the trapping of air which is the major cause of the respiratory impairment. The distinction between the terms chronic bronchitis and bronchiectasis as they are employed in this book is discussed on p. 1551.

The similar confusion which existed some decades ago in the field of heart disease was partially eliminated by a classification which took cognizance of etiologic, morphologic, and physiologic relationships. The following classification is based on a somewhat similar approach. It is not intended to be all-inclusive but is presented to illustrate and clarify the chapters to follow. The third, or clinical, classification is applied only to those disorders which do not fit readily into the etiologic division.

CLASSIFICATION OF CHRONIC LUNG DISEASE

- I. Etiologic
 - A. Congenital
 - B. Specific infective agents
 - C. Allergic
 - D. Physical or chemical agents
 - E. Fibrotic and infiltrative (e.g., sarcoid, amyloid, collagen disease)
 - F. Circulatory
 - G. Neoplastic
- II. Nonspecific, mixed and unknown causes (e.g., the common varieties of chronic bronchitis and of emphysema) (see III for subgroups)

Sinusitis. In the vast majority of cases, acute sinusitis is a bacterial infection brought on by impairment of drainage by the boggy, engorged nasal mucosa of allergic or viral rhinitis. Occasionally, pressure changes of air travel may result in an "aerosinusitis" similar to "aeritis media"; deviations of the nasal septum are contributory.

The manifestations are local pain and tenderness, sometimes with edema of the overlying facial skin, headache, and fever. The headache is worse in the morning, when exudate has accumulated overnight, and tends to improve with upright posture and drainage during the day. If fluid has filled the frontal or maxillary sinuses, they cannot be transilluminated. Treatment consists of analgesics, appropriate antibiotics, and, most important, the establishment of adequate drainage. This last includes reduction of nasal swelling by astringents such as Neo-synephrine or ephedrine, antihistaminics in patients with allergy, and, frequently, aspiration or irrigation of the infected cavity by an otorhinolaryngologist. When coryza or allergic rhinitis runs its course, acute sinusitis usually clears up promptly.

About 10 per cent of antral infections are secondary to dental sepsis or result from fractures of the bony floor during dental extractions.

Complications of acute sinusitis are statistically rare but may be serious. Frank suppuration and abscess may lead to osteomyelitis and spread of infection to the orbit (retrobulbar abscess, cavernous sinus thrombosis), the meninges (see pneumococcal meningitis, p. 892), and brain (via the diploic veins). Surgical drainage of frontal and ethmoid abscesses is sometimes an emergency procedure. About 10 per cent of brain abscesses originate from frontal sinusitis, and infection of the frontal or sphenoid sinus precedes almost every case of subdural empyema (p. 1046). A serious complication of frontal suppuration is osteomyelitis of the skull, recognized by doughy edema of the forehead ("Pott's puffy tumor") and rapid destruction of bone.

With repeated episodes of acute infection, there may be thickening of the sinus mucosa, continual partial obstruction, and chronic inflammation that flares up with the stimulus of even slight obstruction such as that which follows smoking, ingestion of spicy foods, the use of alcohol, or chilly, damp weather. Each acute episode becomes more difficult to control, and the patient may be continuously miserable. Rigid control of exposure to allergens and extremes of temperature, correction of structural defects such as deviated septum, and intensive treatment of acute exacerbations will sometimes bring relief, but radical surgery to ensure free drainage is eventually necessary in many instances.

Chronic sinusitis is especially common in pa-

tients with bronchiectasis (p. 1550), but a causal relationship between lung and sinus disease has not been shown.

Cerebral mucormycosis in patients with diabetic acidosis (p. 1063) usually originates as a sinusitis, invading the orbit and cranium secondarily.

It is important to remember that when a diagnosis of "sinusitis" has been made radiologically, usually distinction between acute, chronic, or inactive disease is not automatically made at the same time; this is also true of x-ray diagnosis of mastoiditis.

Finally, nasal swab cultures are never sterile. Choice of an antibiotic should be based upon the predominating pathogenic organism in cultures of exudate from the sinus; it is fruitless to change antimicrobial drugs as resistant organisms appear in the normal nasal flora of patients taking antibiotics.

DISEASES OF THE LARYNX

The two most important manifestations of laryngeal disease are *hoarseness* and *respiratory obstruction*. Aphasia (p. 376) and aphonia do not signify a lesion of the larynx. *Hoarseness that persists for more than 3 weeks in an adult* calls for intensive investigation, tumor, chronic infection (tuberculosis, mycosis), and vocal cord paralysis being the important possibilities. *Respiratory obstruction* by edema, exudate, foreign body, or bilateral cord paralysis is an acute emergency.

Angioneurotic laryngeal edema is discussed on p. 1267. Among infectious agents, the diphtheria bacillus (p. 934), *Hemophilus influenzae* (p. 954), the viral agents of croup and laryngotracheitis (Tables 180-1 and 180-2, p. 1115), *Treponema pallidum* (p. 1073), the *tubercle bacillus* (p. 1015), and fungi, especially monilia (p. 1062), are the ones most likely to attack the larynx. Laryngitis and hoarseness are not complications of streptococcal pharyngitis; their appearance in a patient with sore throat indicates a viral etiology or complicating diphtheria (formerly a frequent occurrence in streptococcal disease).

Laryngeal papillomatosis is believed by many to be a viral disease. Multiple pedunculated growths on the cords, easily excised but recurrent, are seen exclusively in children. Respiratory obstruction is rare but has occurred. The disease recedes spontaneously at puberty.

Laryngeal acanthosis or hyperkeratosis (*pachydermia laryngis*) causing hoarseness, may be a result of misuse of the voice, smoking, and probably of alcoholism; it is not a precancerous lesion. *Leukoplakia* of the larynx has the same significance in terms of later development of cancer that it has

them unusual or exotic, are characterized by extensive destructive and deforming lesions of the nose and adjacent structures. These include *leprosy* (p. 1020), the *gangosa* and *goundou* lesions of yaws (p. 1082), the *espundia* type of American leishmaniasis (p. 1204), *South American blastomycosis* (p. 1067), *lethal midline granuloma* (p. 1253), and Wegener's granulomatosis (p. 1900).

In *rhinoscleroma*, chronic obstruction of the nasal passages is produced by recurrent, indurated, nonulcerating, inflammatory nodules. Rarely, sinuses or the upper trachea are involved also. The disorder occurs primarily in the Mediterranean countries, South Asia, Indonesia, and Latin America; most cases seen in the United States are in immigrants. Rhinoscleroma is probably an infection, caused by the Von Frisch bacillus, *Klebsiella rhinoscleromatis*, which is always present in the lesions, but the diagnosis is usually established by the pathognomonic histologic finding of masses of atypical plasma cells interspersed with large, foamy Mikulicz cells. Treatment is surgical excision of the recurrent nodules. Untreated, the disease can lead to enormous nasal enlargement with flared nares, the *Hebra nose*.

Rhinosporeidiosis, caused by a yeastlike organism, *Rhinosporeidium scebri*, is common in India and Ceylon, sporadic cases occur in many other areas. Soft, pinkish, sessile or pedunculated polyps appear on the nasal mucosa; sometimes the conjunctivae and, rarely, other mucosal surfaces are involved. Treatment is simple excision.

Rhinophyma or *Pfundase* is a progressive, deforming, nodular enlargement of the alae nasi due to hypertrophy of sebaceous follicles in patients with chronic, severe acne rosacea. There is no specific treatment, plastic repair may be necessary.

Ozena is a severe chronic rhinitis of unknown cause characterized by thick, greenish discharge, mucosal crusts, turbinate atrophy, and an offensive odor. Patients eventually become anosmic. Even when the nasal passages are widened and resistance to airflow is decreased, obstruction is a constant complaint. Cultures grow gram-negative bacilli (*Klebsiella*, *Pseudomonas*, etc.). Treatment with local or systemic antibiotics and large doses of vasodilators (Priscoline, nicotinic acid) will often reduce the discharge without halting the atrophy. Most important for these unfortunate patients, the odor is lessened or eliminated in many instances.

Mycosis leptothrix (so-called because infection by *Leptothrix* was thought to be its cause) is a focal hyperkeratosis of the tonsils, pharynx, and larynx that occurs in young adults. The many small, white, raised patches over the mucosa are striking and are often mistaken for exudate; removal causes no bleeding. Patients are sometimes asymptomatic but may complain of "scratchy" throat. There is no

treatment; the lesions regress after months or years.

Pharyngeal bursitis, or Tornwaldt's disease, is bacterial inflammation of a small recess in the posterior nasopharyngeal wall which sometimes persists into adulthood. Obstruction of the neck of the pouch leads to infection and abscess formation. Treatment consists of antibiotics followed by surgical excision of the bursa rather than simple drainage.

Recurrent, profuse epistaxes occur with hypertensive vascular disease, familial telangiectasia (p. 1321), coagulation defects (p. 1318), and tumors. *Basal cell carcinoma* of the nares and septal *hemangioma* are relatively common. Carcinomas of the nasal mucosa are unusual; they occur in elderly individuals and are late to invade or metastasize.

Carcinoma of the nasopharynx (so-called lympho-epithelioma) occurs in young and middle-aged adults and is especially common among Chinese. These tumors metastasize very early. Large, cancerous cervical lymph nodes often result from a primary lesion so small that it is found with great difficulty. These tumors tend to occur near the orifice of a eustachian tube, and the combination of cervical adenopathy and ipsilateral ear pain or deafness is a signal for careful examination of the nasopharynx. These tumors are radiosensitive, and survival for several years with repeated courses of therapy is usual; complete cures are rare.

Lymphoma and *reticulum cell sarcoma* are often first detected as nasopharyngeal masses. Isolated *plasmacytomas* of the nasopharynx are found predominantly in elderly males, some of whom develop multiple myeloma (p. 1342). Two tumors of children deserve mention. A highly malignant and rapidly fatal lesion which tends to arise in the nasopharynx or soft palate is the *sarcoma botryoides* or *embryonal rhabdomyosarcoma*. Juvenile *angiofibroma* is a benign growth that occurs almost exclusively in young boys, arising from the base of the sphenoid and filling the nasopharynx. Sometimes the tumor will regress during puberty but excision is usually necessary. These tumors bleed spontaneously, and profuse hemorrhage is very likely to complicate surgical manipulation.

DISEASES OF THE PARANASAL SINUSES

The mucosa of the ethmoid and maxillary sinuses may become involved by the polyposis that occurs in patients with allergic rhinitis (p. 1259). While primary tumors of the sinus mucosa are rare, encroachment by neoplasms arising in contiguous structures is common and easily visualized by x-ray. *Osteoma of the frontal sinus* is the most frequent lesion of this type; neoplasms of the maxilla and mixed tumors of the salivary gland type arising in the palate invade the antrum.

by intermittent, reversible increases in airway resistance due to excessive mucous secretion and smooth muscle spasm and is associated with paroxysmal shortness of breath and wheezing respiration. Obstruction to air flow may vary and improve spontaneously or with the use of bronchodilator drugs, including corticosteroids. Bronchial asthma is discussed on p. 1263 and the differential diagnosis of asthma and emphysema on p. 1521.

Airway obstruction caused by excessive secretions as a result of infection is the other important cause of reversible airway obstruction. Varying degrees of reversible obstructive lung disease may coexist with irreversible obstructive lung disease, chronic bronchitis, or both, and the amount may be accurately quantified by simple pulmonary function tests.

Irreversible obstructive lung disease refers to irreversible generalized narrowing of the bronchial tree and increased airway resistance which has persisted for more than 1 year, unaffected by treatment including bronchodilator drugs as well as corticosteroids. The majority of such patients will be found to have emphysema at postmortem examination. A few reveal only varying combinations of chronic bronchial asthma, chronic bronchitis, or tubular bronchiectasis. The British make a diagnosis of "irreversible obstructive lung disease," appending "with emphysema" if the clinical picture warrants the anatomic statement.

The above definition and classification of chronic nonspecific lung disease was developed by British authorities to supplant the irrational use of the terms chronic bronchitis, asthma, and emphysema. It is presented here because it stresses (1) the use of functional rather than anatomic diagnosis clinically and (2) the difficulties in the accurate diagnosis of emphysema and the various combinations of bronchitis, reversible and irreversible obstructive lung disease which may occur during life. In the discussion that follows, chronic bronchitis and obstructive emphysema will be considered as such, as is the practice in the United States.

CHRONIC BRONCHITIS

Occurrence. Chronic bronchitis marks its onset usually between the ages of thirty and sixty years. There is a preponderance in men of approximately 4:1. In England there exists an inverse relationship between the social scale and the incidence of the disease—the laboring classes being the most commonly afflicted, the professional classes least so. The death rate also rises steeply from rural to urban and highly industrialized areas, suggesting that atmospheric pollution plays an important role. It is possible that the disease is more common and more severe in England than in the United

States because of the damp, cold climate and degree of atmospheric pollution in England, both of which aggravate the symptoms. However, the only epidemiologic study carried out in the United States (Pemberton) indicated that the prevalence of uncomplicated bronchitis was similar in the two countries. The presently available figures indicate greater disability and far higher mortality from the disease in England as compared with North America. In England it is the commonest cause of death and morbidity among all respiratory diseases, including pneumonia, tuberculosis, asthma, and lung cancer.

Etiology. The disease may be insidious in onset, or it may follow a bout of acute pneumonia or bronchitis or well-established bronchial asthma. A possible etiologic relationship has been suggested for bronchiectasis and pulmonary tuberculosis because of their frequent association with chronic bronchitis. In the United States the disease is associated with a history of heavy cigarette smoking in more than 75 per cent of patients. Present evidence favors the theory that exposure to irritants (cigarette smoke, air pollutants) in the susceptible individual leads to chronic hypersecretion of mucus in the bronchial tree.

Pathology. The most important lesion in chronic bronchitis is hyperplasia and hyperactivity of the mucus-secreting glands in the trachea and bronchi and of the goblet cells of the bronchial epithelium. The bronchial wall may show varying degrees of chronic inflammation with focal scars. Many older patients with a long history of chronic bronchitis will show, in addition, the changes of emphysema at postmortem examination, even though this may not have been clinically manifest as breathlessness (associated with the symptoms of chronic bronchitis) during life.

Clinical Manifestations. The patient consults the physician because of (1) cough and expectoration, (2) an acute respiratory infection, (3) breathlessness, which usually signifies the association or onset of complicating bronchospasm (asthma) or obstructive emphysema, or (4) fear of cancer. The chronic productive cough is usually attributed to cigarette smoking or is dated from childhood or an attack of influenza. The sputum is ropy, white, and elastic and varies in amount from a few milliliters to several ounces daily. During superimposed infections ("chest colds") cough and sputum increase and the secretions become yellow or yellow-green and occasionally bloodstreaked. The symptoms are worse in the winter, in the morning on awakening, and at the end of the day; with changes in barometric pressure and humidity; on exposure to dusts, air pollution, and cigarette smoking; in crowds and after excessive talking and alcohol ingestion. Severe paroxysms of coughing may occur

elsewhere and calls for local excision. It is important not to confuse *acanthosis* and *leukoplakia*.

The so-called singers' nodule or amyloid nodule is a lesion of the vocal cord that appears almost exclusively in white males over the age of thirty years who have strained or misused their voices. Treatment is excision; the lesion does not recur. Incidentally, the lesion contains no amyloid.

Carcinoma of the larynx is ten to twelve times more common in men than in women; the average age at which it appears is sixty years. Tumors arising on the vocal cords are classified as "intrinsic" and constitute 70 per cent of the lesions, those extending beyond the cords are "extrinsic." Hoarseness is an early symptom with intrinsic cancer; it is often delayed in the extrinsic type. Treatment varies, but radiation alone is recommended only for small lesions of the middle third of the cord. Laryngectomy is the treatment of choice for all other cancers; preoperative radiation and extensive removal of lymph nodes are used in many clinics.

Among the many causes of partial or complete paralysis of the vocal cords are pressure by aortic aneurysm, mediastinal tumors, metastatic esophageal cancer, postdiphtheritic neuritis (p. 985), poliomyelitis (p. 1139), and operative trauma (especially thyroidectomy). If a nerve is cut at operation, there will be sudden stridor; if stretching and edema are affecting the nerve, the onset of stridor and hoarseness will be gradual. Bilateral injury may cause sudden obstruction, necessitating tracheostomy.

260 CHRONIC BRONCHITIS AND EMPHYSEMA (Chronic Nonspecific Lung Disease)

John H. Knowles

The problem of chronic nonspecific pulmonary disease, consisting mainly of chronic bronchitis and obstructive emphysema, has become the most important one in the field of pulmonary disease from all standpoints, including prevalence, morbidity, mortality, and economic loss. Knowledge of these conditions has been incomplete and uncertain for a number of reasons. A persistent cough has been accepted as a normal phenomenon in the cigarette smoker, and rarely is the physician consulted for this complaint alone. Because of the length of time required for all the dire consequences of chronic bronchitis to unfold and because it frequently accompanies a more dramatic illness, such as bronchogenic carcinoma, pneumonia, or peptic ulcer, it has been relegated to a position of secondary importance by lay people as well as the

medical profession. Clinically, the differentiation of asthma, chronic bronchitis, and the various types of emphysema (senile, "compensatory," obstructive, for example) has been difficult because of confusion concerning the etiologic significance of the barrel chest, "smoker's cough," and wheezing respiration (the patient compounds this felony by announcing that he has "asthma"), the inadequacies of radiologic diagnosis in these conditions, and generally, the unqualified use of the word emphysema, to denote anything from the kyphotic chest deformity of old age to the hyperinflated chest of the child with acute bronchial asthma.

DEFINITIONS AND CLASSIFICATION

Chronic diffuse nonspecific lung disease refers to a condition of chronic cough with sputum production with or without paroxysmal or persistent uncomfortable shortness of breath, which cannot be attributed to localized lung disease, generalized pulmonary infection, granulomatous, fibrotic, or collagen disease of the lung, pneumoconiosis, primary cardiovascular disease, disorders of the chest wall, or psychoneurosis. It may coexist with any of these conditions and not infrequently does. In such instances two diagnoses should be made. There are two main categories of chronic diffuse nonspecific lung disease: chronic bronchitis and generalized obstructive lung disease.

Chronic bronchitis has been arbitrarily separated from recurrent acute bronchitis in epidemiologic studies as "cough with production of sputum occurring on most days for at least 3 months in the year during at least 2 years." The sputum may be mucoid or purulent. Chronic bronchitis predisposes to recurrent respiratory infection, particularly during the winter months, and eventually may lead to dyspnea by virtue of a gradual loss of ventilatory capacity due to the development of emphysema. The smoker's cough, when it conforms to the above description, is an example of chronic bronchitis.

Generalized obstructive lung disease is a condition characterized by increased airway resistance due to diffuse narrowing of the bronchial tree. This is the result of hypersecretion, smooth muscle spasm, a check-valve mechanism, bronchiolar fibrosis, or all four of these factors. It is diagnosed simply and with certainty by finding a reduction in the timed vital capacity (one second forced expiratory volume—F.E.V._{1.0} in British terminology) or maximal midexpiratory flow rate. The severity of dyspnea depends on the degree of obstruction.

Generalized obstructive lung disease is subdivided into reversible and irreversible forms.

Reversible obstructive lung disease is chiefly caused by bronchial asthma, which is characterized

pansion of lung (by virtue of negative intrapleural pressure) to fill the empty space created by removal or shrinkage of lung tissue. It has been called overdistention or compensatory emphysema in the past. It is not possible to relate pulmonary disability or insufficiency to this phenomenon, nor is there any evidence that it leads to destructive or obstructive changes in the area involved, either pathologically or by pulmonary function test. Following pneumonectomy, for example, the remaining lung overdistends without the occurrence of dyspnea or disability.

Panacinar dilatation emphysema occurs distal to partial bronchial obstruction. Partial bronchial obstruction becomes complete with the normal narrowing of the bronchus in expiration and air is trapped. Pulmonary function shows chiefly obstruction to air flow, which is variable in amount depending on how early in expiration the obstruction becomes complete. The main significance of this type of panacinar dilatation emphysema is that its discovery as an area of increased radiolucency in the lung fields by x-ray may be the first sign of bronchogenic carcinoma.

Selective Distribution—Focal Emphysema. This is a disease of coal workers. Inhaled dust is deposited around the respiratory bronchiole, eliciting fibrosis and atrophy of smooth muscle. Coal-worker's pneumoconiosis is the only known form of dilatation emphysema localized to the respiratory bronchiole, hence the term focal emphysema. There may be no symptoms and minimal or no change in pulmonary function. In advanced cases, however, the clinical picture of obstructive emphysema may appear. The x-ray shows diffuse bilateral nodulations. The disease is described in greater detail on p. 1547.

Aging Lung Emphysema. This third category of dilatation emphysema is added here with the presumption that aging results in loss of elasticity of pulmonary tissue, leading to dilatation of air spaces. A change in the size of air spaces with advancing age has not been demonstrated pathologically as yet; however, changes in pulmonary function as a result of aging are well established. These changes suggest a state of hyperinflation of the lung and mild obstructive emphysema. There is an increase in residual lung volume, decrease in maximal breathing capacity and mild increase in airway resistance, decrease in arterial oxyhemoglobin saturation, and mild maldistribution of inspired air. More air is contained in the aged than the youthful lung at the same intrapleural pressure, indicating loss of elasticity of the lung and presumably, therefore, dilatation of air spaces. No definite symptoms or disability can be attributed to these changes alone in the otherwise healthy elderly individual.

The term "senile emphysema" has not been used

above because it should be reserved to refer to changes in the thoracic cage with age and not to pulmonary changes. Loss of water and disorganization of the cartilaginous intervertebral disks result in a kyphotic distortion of the thoracic spine, in turn resulting in rotation of the ribs so that the anterior chest is thrown out and up and assumes the barrel shape. Pulmonary function is unimpaired save for the minor changes expected as a consequence of normal aging (above), and dyspnea and disability should not be attributed to this skeletal deformity alone. The aged individual, although showing the functional changes described above, may or may not have an accompanying dorsal kyphosis.

Emphysema Due to Destruction of the Walls of Air Spaces

Unselective Distribution—Panacinar Destructive Emphysema. The word panacinar refers to uniform dilatation of all air passages distal to the terminal bronchiole. The lesions may be localized or widespread and vary in different parts of the lung.

Selective Distribution—Centrilobular Destructive Emphysema. This type of emphysema selectively affects the respiratory bronchiole, resulting in dilatation of air spaces in the proximal portion of the acinus, i.e., there exists a state of bronchiolectasis. Lesions may be local or widespread.

Irregular Distribution—Irregular Emphysema. Irregular emphysema refers to the dilatation and destruction of air spaces seen adjacent to scars or in diffuse fibrotic disease such as the Hamman-Rich syndrome. As such it may occur anywhere in the acinus and hence the term "irregular." The word focal should not be used here as it refers specifically to dilatation of respiratory bronchioles associated with coal-worker's pneumoconiosis.

Panacinar and centrilobular destructive emphysema may be seen singly or together in the same lung, and it is these pathologic forms which are demonstrated in subjects with obstructive pulmonary emphysema (see below). They cannot as yet be differentiated clinically. Blebs and bullae can be seen in any type of destructive emphysema, and therefore the term "bullous emphysema" should not be used to imply a special form of the disease.

Obstructive Pulmonary Emphysema

Obstructive pulmonary emphysema is a disease that affects predominantly men between the ages of forty-five and sixty-five years. It is usually preceded by chronic bronchitis and is characterized by dyspnea on exertion, hyperinflation of the chest, irreversible obstruction to airflow, and destruction and dilatation of the walls of air spaces.

Etiology. Because of the association of chronic bronchitis as a concomitant event or as one pre-

nocturnally or on awakening in the morning. Post-nasal drip and symptoms suggestive of chronic sinusitis are frequent. Acute chest pain may be due to rib fracture incurred during severe coughing, to pleurisy associated with a complicating pneumonia, or to muscular strain around the lower costal margins. Syncope may occur during a sudden fit of coughing (tussive syncope, p. 308). Vigor is usually well maintained, and there is no loss of appetite or weight. Dyspnea is not a feature of uncomplicated chronic bronchitis.

Physical examination is remarkable for the lack of positive findings. The nose may contain crusted purulent material, and the nasal and pharyngeal mucosa may be fiery red, raw, and dry appearing, and the uvula, slightly edematous. The patient clears his throat frequently, and deep breathing may result in a violent fit of coughing. The lungs may be clear, or there may be scattered basilar rales and transient rhonchi, frequently clearing with cough. The heart is normal. There is no clubbing of the fingers.

Blood counts and radiologic examination of the chest and paranasal sinuses are usually completely normal. Culture of sputum may yield pathogenic organisms, most commonly the pneumococcus or *Hemophilus influenzae*. *Staphylococcus aureus* and gram-negative organisms are found occasionally, and the hemolytic streptococcus is remarkable for its rarity. Pulmonary function may be completely normal, or there may be slight reduction in timed vital capacity (80 to 75 per cent in the first second as compared with greater than 80 per cent normally) or maximal midexpiratory flow rate (e.g., 1.5 to 2.0 liters per sec as compared with greater than 3 liters per sec normally) and maximal breathing capacity (55 to 70 liters per min in contrast to 100 liters per min or more, normally).

Bronchoscopy and bronchography may be necessary to rule out other causes of chronic cough such as tumor, bronchiectasis, and foreign body. At bronchoscopy, the tracheobronchial mucosa is usually hyperemic and redundant. Bronchography may show diverticula on the inferior surface of the main stem and primary segmental bronchi which represent the filling of the dilated ducts of mucous glands. Beading of the bronchial lumen may be observed because of excessive mucus, or there may be an accordion-like appearance due to shortening of the bronchus with heaping up of redundant mucosa. Failure of peripheral filling and dilated bronchioles presenting as peripheral "pools" of dye may be seen in long-standing cases and probably indicate coexistent emphysema. Occasionally an area of tubular bronchiectasis is found. The differentiating features of bronchitis and bronchiectasis are discussed on p. 1551. The diseases may coexist, and some observers believe that local bron-

chiectasis may lead to diffuse chronic bronchitis elsewhere in the lung. There is, however, no evidence that bronchitis has been cured by resection of localized bronchiectasis.

The course of chronic bronchitis is not completely known as there have been no studies of its natural history spanning more than several years. It seems clear, however, that subjects with chronic bronchitis often continue to have their symptoms for many years without further complication and die of some totally unrelated disease. Others suffer repeated respiratory tract infections and develop paroxysmal, reversible obstructive pulmonary disease (bronchial asthma). In this group as well as in a number of patients who remain noninfected and produce minimal sputum ("dry" bronchitis), there arise a certain number who ultimately develop obstructive emphysema.

EMPHYSEMA

The term emphysema is derived from the Greek and means to blow into or inflate. *Subcutaneous emphysema* occurs with soft tissue infection with gas-forming organisms such as colon and Welch bacilli. It is also seen in the area of the incision following thoracotomy or with dissection of air from mediastinal emphysema. *Interstitial emphysema* refers to the escape of air from alveoli into the interstices of the lung where it dissects along vascular sheaths into the mediastinum to give rise to *mediastinal emphysema*, which, in turn, can also result from perforation of the thoracic esophagus. *Senile emphysema* refers not to a primary disease of the lungs but to a degenerative disease of the thoracic spine occurring in elderly individuals (see below).

Pulmonary emphysema is characterized pathologically by increase in the size of the air passages distal to terminal bronchioles due to dilatation or destruction of their walls. Further subdivision includes the factor of distribution, e.g., *selective* as occurs in the focal emphysema due to dust versus *unselective* as with the dilatation of air spaces seen in pulmonary tissue adjacent to a resected area ("compensatory emphysema"). The classification adheres to the recommendations of the Ciba Guest Symposium and is slightly modified.

Emphysema Due to Dilatation Alone

Unselective Distribution—Panacinar Dilatation Emphysema. There are two main conditions in this category: (1) compensatory or overdistention emphysema and (2) emphysema secondary to partial bronchial obstruction as with foreign body or bronchogenic carcinoma. The term panacinar means that all the air spaces distal to the terminal bronchiole are affected.

Panacinar dilatation emphysema results from ex-

Clinical Manifestations. The typical patient gives a history of chronic bronchitis. Frequent respiratory infections have occurred, usually during the winter months, characterized by febrile episodes with increase in purulent sputum. Finally, at some point after years of bronchitic symptoms, breathlessness on exertion makes its appearance. Early in the course, dyspnea may occur only during the winter months with exacerbations of infection and is due to partially reversible ventilatory defects, i.e., bronchospasm and excessive secretions. Later, dyspnea on exertion becomes firmly established, persists the year around, and signifies the development of irreversible obstructive ventilatory defect. Of all the clinical clues, persistent breathlessness is the most reliable sign on which to establish a presumptive diagnosis of obstructive emphysema. The clinical diagnosis cannot be made in its absence even though many patients with chronic bronchitis and no dyspnea may be found at postmortem examination to have mild emphysema.

The onset may be acute, and breathlessness is dated from an episode of pneumonia or severe, acute bronchitis. In some subjects, this is the easily remembered episode in what really is a long history of slowly progressive bronchitis. In other patients, breathlessness and cough have been accepted as concomitants of "getting old" or of smoking. The disease may come to the physician's attention in a number of ways: (1) by the development of acute respiratory failure with acute bronchitis or pneumonia, or during the postoperative period following intubation, atropine, and morphine—when the retrospective history of chronic cough and dyspnea is finally obtained and its significance fully appreciated; (2) by the development of bronchogenic carcinoma; (3) by the development of inguinal hernia because of chronic cough; and (4) because of the occurrence of the symptoms or complications of peptic ulcer (see below). The disease may be so insidious in development that the diagnosis is not established until post-mortal examination.

Other complaints are frequent. Because of limitation of activity the patient may gain weight initially, but later anorexia leads to loss of weight. Vigor is lost, and sleep is difficult. As the disease becomes more severe, changes in the arterial blood gases occur and cor pulmonale develops.

Physical signs may scarcely be more notable in the early phase of the disease than those seen in the patient with uncomplicated chronic bronchitis. In the moderately ill patient who exhibits no alteration in the blood gases at rest, the following signs are likely to be noted. The patient appears dyspneic with exertion. The fingers may be tobacco stained, but are usually not clubbed. The eyes are prominent. The neck veins distend on expiration.

The chest is fixed in the hyperinflated, inspiratory position, and the flesh about the neck and supraclavicular spaces is sunken. The accessory muscles of respiration, particularly the sternomastoids, are large and active during inspiration, and the trachea descends markedly on maximal inspiration. Lower rib margins may flare outward, and the subcostal angle is wide. There is frequently a dorsal kyphosis. Prominent cutaneous venules are seen anteriorly and laterally around the lower costal margins. During inspiration, the chest moves *en bloc* instead of "unfolding" from below upward during expansion. Expiration is prolonged. Cardiac and hepatic dullness are impaired or even absent, and heart sounds are distant. The pulmonary second sound is prominent and may be split, particularly on expiration. The percussion note of the chest is hyperresonant, and the diaphragms are low with minimal or absent excursion. The breath sounds are distant or even absent and when heard have a more bronchovesicular than vesicular quality. Occasional early inspiratory ("opening") rales are heard at the bases. Expiratory wheezing during spontaneous respiration is heard only if excessive secretion or bronchospasm is present. The impulse of the heart is prominent in the epigastrium, and the sounds are best heard here. The liver is displaced downward, and the edge easily palpable. The abdominal muscles are lax. A decline in arterial pressure during inspiration may be observed, but the veins continue to display inspiratory collapse. Thus the complete picture of the paradoxical pulse (see p. 1468) is lacking.

Röntgenography is of little help in diagnosis until the disease is advanced, at which time the following picture is seen. The thoracic cage is large with low diaphragms, an apparent horizontal position of the ribs, and wide intercostal spaces. Prominent soft tissue shadows may indicate hypertrophy of the pectoralis muscles. The heart lies vertically and appears small. The mediastinal shadow is elongated. The hilar vascular shadows may be prominent, but the peripheral vessels are small and appear reduced in number. Thin-walled areas of translucency in which no vascular shadows can be seen represent blebs and bullae and are seen commonly at the apices and bases of the lungs. Nodular or linear areas of scarring and fibrosis may be seen, but generally the lung fields are notable for their radiolucency. In the lateral projection, an increase in size of the thoracic cage and a dorsal kyphosis are present. The retrosternal and retrocardiac air spaces are increased. Fluoroscopy is vital to the diagnosis, and the best radiologic sign is reduction in the excursion of the diaphragm. Air trapping is demonstrated on rapid expiration by areas of local radiolucency. Tomography

ceding the onset of exertional dyspnea in over 70 per cent of patients, most observers have favored this disease as the inciting factor. The cause of chronic bronchitis is unknown, but because of the high association of cigarette smoking with bronchitis and emphysema, an etiologic role has been assigned to cigarettes. This may be so, just as the cold damp weather and a dusty working or polluted urban environment may also lead to hypersecretion of mucus in the bronchial tree and ultimately obstructive emphysema. In short, the etiologic factors of chronic bronchitis apply equally well to patients with obstructive emphysema. Dyspnea in the patient with chronic bronchitis usually signifies either reversible bronchial narrowing due to secretions or bronchospasm or irreversible obstruction to airflow due to the development of destructive emphysema. It may well be that the development of obstructive emphysema results from gradual extension of chronic bronchitis into the bronchioles, perhaps accelerated by repeated bouts of secondary bacterial infection. In some this sequence of events is obvious, but in others it must be assumed that the process is subclinical and smolders over a period of many years. Obstructive emphysema is due partly to the destructive effects of chronic bronchiolitis per se and partly to the distending effect of air trapped distal to the obstructing lesions. The theory that a primary degeneration of pulmonary elastic tissue initiates the disease has been abandoned.

The etiologic role of bronchial asthma remains obscure, but the few careful studies reported indicate that it rarely progresses to obstructive emphysema. Part of the confusion on this point has arisen from the difficulties of differentiating obstructive emphysema with attacks of bronchospasm from bronchial asthma (see below).

Several investigators have pictured emphysema as an abnormal acceleration of the aging process because of the functional changes resembling a mild state of emphysema seen regularly in most elderly individuals (above).

The finding of high concentrations of sodium and chloride in the sweat of a few patients with obstructive emphysema, similar to the abnormal pattern demonstrated in childhood fibrocystic disease of the pancreas (see p. 1666), has led to the suggestion that secretion of abnormally viscid mucus in the bronchial tree with resultant obstruction and infection of the bronchioles might explain the pathogenesis of some instances of emphysema.

Regardless of one's opinion concerning the role of smoking in chronic bronchitis, there remain approximately 10 per cent of patients who deny chronic productive cough ("dry emphysema") and perhaps 20 per cent who have never smoked. In

some a family history of chronic bronchitis is obtained, in others, repeated bouts of pneumonia. In some individuals, preexisting localized bronchiectasis or long-standing pulmonary tuberculosis seems to have been complicated by slow superimposition of diffuse, chronic bronchitis and obstructive emphysema.

Because of the many and diverse associated conditions and possible etiologic factors, it is important at the present time to consider obstructive emphysema to be a syndrome as well as a disease. In addition to the above conditions, a number of known disease processes can produce or be associated with a picture which is clinically and physiologically indistinguishable from the "idiopathic" disease. These include silicosis, coal-worker's pneumoconiosis, sarcoidosis, bronchogenically disseminated tuberculosis, and some cases of kyphoscoliosis. In these instances localization of the disease process at the level of the respiratory bronchiole or associated chronic bronchitis gives rise to chronic irreversible obstruction of air flow and the picture of obstructive emphysema. All these conditions must be considered in diagnosis when the patient with apparent chronic bronchitis and obstructive emphysema is seen.

Pathology. Classically the lungs are large and do not collapse when the thorax is opened. Blebs (subpleural air collections) and bullae (parenchymal emphysematous spaces with a diameter greater than 1 cm) may be noted, as well as generalized dilatation of air spaces. Nodular areas of scarring and fibrosis may be visible subpleurally. If the lung is fixed under a constant head of distending pressure, centrilobular or panacinar types of emphysema may be distinguished in nearly equal frequency. Microscopically there are seen chronic bronchiolitis and peribronchiolitis, ulceration of the epithelium, intraluminal granulation tissue, and fibrosis. Smooth muscle may be hypertrophied. The lumen of the bronchiole supplying areas of emphysema is often narrowed but may be normal or even dilated. The distal alveoli are obliterated and larger air spaces formed, presumably by confluence of alveoli and increased by air trapping due either to check-valve mechanism or collateral ventilation. Loss or degeneration of alveolar elastic tissue is seen. The number of visible capillaries is reduced because of destruction of alveolar walls. Foci of intrabronchiole mucus ("mucous plugging") and pus are seen as are occasional areas of pneumonia. Besides reduction in capillary bed, there may be marked enlargement of the bronchial venous system. The evidence is not convincing that the bronchial arterial system is diseased. Obstructive emphysema is the commonest cause of cor pulmonale (see p. 1537).

out demonstrating obstruction to air flow. Persistent dyspnea on exertion and depression of breath sounds are the cardinal features. Restriction of diaphragmatic motion correlates best with the severity of the process. The finding of radiolucency and a large chest does not in itself establish the diagnosis.

Once the diagnosis has been established, the degree of reversibility or irreversibility must be determined by measuring the timed vital capacity before and after the use of a suitable bronchodilator such as aerosolized isoproterenol hydrochloride. In occasional patients with chronic intrinsic bronchial asthma, intensive treatment with corticosteroids may be necessary to achieve maximal reversal of the obstructive ventilatory defect.

If the patient has bronchial asthma, certain features may suggest this diagnosis, namely, family history of allergic disease, lack of smoking because of aggravation of asthmatic symptoms, positive skin tests, peripheral blood eosinophilia and, most important, intermittency of symptoms and spontaneous reversibility to normal or near normal of abnormal pulmonary function or with the use of bronchodilators, including corticosteroids. The pulmonary diffusing capacity is normal in uncomplicated asthma and reduced in obstructive emphysema; thus differentiation is possible. The differentiation of emphysema and pulmonary congestion due to heart disease is discussed on p. 1380.

The treatment of chronic nonspecific pulmonary disease (bronchitis and emphysema) and of respiratory failure is discussed on p. 1573.

261 RESTRICTIVE PULMONARY DISEASES AND DISORDERS OF PULMONARY DIFFUSION

Eugene Robin

RESTRICTIVE DISEASES

Restrictive pulmonary diseases are characterized by a significant decrease in the expansibility of the lungs. Restrictive factors are important in many different kinds of pulmonary disease. This section will be devoted to a discussion of disorders in which a restrictive ventilatory defect is the major abnormality. The physiologic abnormalities characterizing such disorders are a reduction in all lung volumes without evidence of airflow obstruction or of abnormality in intrapulmonary gas mixing.

A major consequence of restrictive pulmonary disease may be the development of alveolar hypoventilation, the manifestations of which frequently dominate the clinical picture. Alveolar hypoventilation has already been discussed (p. 109). It exists when alveolar ventilation is insufficient to maintain normal alveolar gas tensions. It is therefore characterized by a low mean alveolar O_2 tension and a high alveolar CO_2 tension, resulting in corresponding abnormalities of pulmonary capillary blood, arterial blood, and ultimately of tissue gas tensions. Since the adequacy of gas exchange is based on measurements of arterial blood gases, the cornerstone of alveolar hypoventilation is an elevated arterial CO_2 tension (Pa_{CO_2}).

The physiologic and clinical consequences of alveolar hypoventilation are related to the associated hypoxia and hypercapnia. With hypoxemia of sufficient magnitude cyanosis is apparent. Hypoxic stimulation of the bone marrow produces polycythemia. The presence of hypoxia and hypercapnia may produce an increase of cerebrospinal fluid pressure with or without papilledema by unknown mechanisms. Chronic hypercapnia leads to bicarbonate retention by the kidney, resulting in an increased concentration of this anion in extracellular fluid. Chronic hypercapnia likewise leads to a depression of respiratory center sensitivity to the normal stimuli of CO_2 and pH, thus accentuating the degree of alveolar hypoventilation. Periodic breathing of the Cheyne-Stokes variety is common and likewise reflects respiratory center depression. The combination of hypoxia and hypercapnia may lead to mental symptoms. Prominent among these is somnolence, which may constitute the patient's chief complaint. There is no clear-cut relationship between the degree of hypercapnia and the degree of somnolence. There may be marked hypercapnia without somnolence or somnolence with only minor degrees of hypercapnia. With acute rises in CO_2 ,

occasionally be helpful in delineating vascular changes such as prominent hilar vessels, small and fewer peripheral vessels, or absence of vessels in bullous lesions.

Blood counts and urinalysis are normal. The electrocardiogram is normal in uncomplicated cases; it may reveal a loss of the usual tendency to left axis deviation seen in older individuals. The sputum has been described. Sputum cell counts usually reveal lymphocytes or polymorphonuclear leukocytes, but occasionally eosinophiles are numerous (see below). The results and use of pulmonary function tests are described below.

Pathophysiology. Obstruction to air flow as a result of granulating and fibrosing bronchitis and expiratory closure of loosely supported respiratory bronchioles, coupled with degeneration of elastic tissue, result in hyperinflation of the lung. This is demonstrated by finding an increase in functional residual capacity, residual volume, and residual volume to total lung capacity ratio. The work of breathing is increased because of increased airway resistance. Timed vital capacity, maximal mid-expiratory flow rate, and maximal breathing capacity are reduced in proportion to the degree of obstruction and therefore correlate well with the severity of dyspnea. If a partially reversible ventilatory defect exists because of acute infection or bronchospasm, these tests will indicate improvement with effective therapy. Obstructing lesions vary throughout the lung, and therefore abnormalities of distribution are seen, including maldistribution of inspired air, venous admixture, and dead space effects (p. 112). Areas perfused with blood but poorly ventilated cause increased venous admixture of arterial blood ("physiological shunting"); other areas, including bullous lesions, are ventilated but not perfused, leading to dead space effect. Cardiac work is wasted in the first situation and ventilatory work in the second instance. Both pumps have to increase their work to compensate. Increased ventilation of well-perfused areas can compensate for the shunted carbon dioxide and maintain a normal CO_2 tension of arterial blood. It cannot add appreciable amounts of oxygen to the blood, however, to compensate for hypoxemia (p. 111). This is due to the difference in the shapes of the CO_2 and O_2 dissociation curves and explains the sequence of changes in arterial blood gases, beginning first with mild arterial oxygen unsaturation and normal CO_2 contents and tension. As the disease becomes more severe, hypoxemia increases, and finally alveolar hypoventilation results in CO_2 retention, with respiratory acidosis. Earlier in the disease, the increased requirements of gas exchange necessitated by exercise may result in unsaturation of blood, normally saturated at rest.

As the disease progresses and continued destruc-

tion of pulmonary capillary bed occurs, the pulmonary diffusing capacity falls and the pulmonary vascular resistance rises. Hypoxemia stimulates erythropoiesis and causes secondary polycythemia. It also leads to pulmonary vasoconstriction and an increase in arterial resistance. The work of the right heart is increased and cor pulmonale ultimately ensues, signifying the final and most advanced stage of the illness (p. 1537).

Course of the Disease. The course of the disease is extremely variable, and prognostication is difficult. At any time, superimposed pulmonary infection causes an increase in the severity of the disease due to further reduction in functioning lung tissue because of consolidation, secretions, or bronchospasm. The course may be a rapidly malignant one with death in respiratory failure in a matter of several years, or the duration from onset of dyspnea may be as much as 20 or 30 years with death due to intercurrent disease. The occurrence of hypoxemia and hypercapnia or the development of cor pulmonale are bad prognostic signs, and death usually occurs within several years of their onset. Mild hypoxemia by itself does not carry such a dire prognosis.

Respiratory failure is said to have occurred when the lung can no longer provide for normal gas exchange and CO_2 retention and arterial oxygen unsaturation are the result. As hypoxemia supervenes further weight loss may occur, and when CO_2 retention follows, headache, difficulty in concentrating, drowsiness, and confusion are common findings. In the presence of cor pulmonale with right heart failure, papilledema may be seen. There may also be a curious inability to sustain a posture (asterix, "flapping tremor") identical with that observed in hepatic insufficiency or uremia. This is particularly common in acute respiratory failure. Respiratory failure may occur insidiously without obvious precipitating event but commonly occurs because of acute respiratory infection, administration of sedative, narcotic, or anesthetic agents, or heart failure. Administration of oxygen is absolutely necessary but may be hazardous (see p. 1575).

The association of peptic ulcer and emphysema appears to be more than fortuitous. About 20 per cent of patients with emphysema have a peptic ulcer, usually duodenal in location, and the incidence of emphysema is two to three times as common in patients with peptic ulcer as in the normal population. Whether common psychic factors, cigarette smoking, or hypoxia are important etiologic factors is unknown, but it is important to keep the relationship in mind.

Diagnosis. Obstructive pulmonary emphysema is misdiagnosed frequently. Physical signs, except in advanced cases, are notoriously misleading and unreliable. The diagnosis should not be made with-

related to the decreased sensitivity of the medullary respiratory center to the CO_2 -pH stimulus following prolonged hypercapnia. This factor can be demonstrated by chronically exposing normal subjects to increased concentrations of CO_2 in the inspired air. After a period of several weeks under these conditions, there is a decrease in the ventilatory response to CO_2 , even in the absence of obstruction.

The relative importance of mechanical and chemical factors in the genesis of CO_2 insensitivity in obstructive emphysema is not clear. However, it seems certain that chemical factors play an important role in some patients. This is best seen in the syndrome called "carbon dioxide narcosis," which occurs in patients with chronic hypercapnia and hypoxia. When the degree of hypoxia is decreased by the administration of high concentrations of oxygen, and without any change in respiratory mechanics, there follows the development of confusion, coma, and profound hypoventilation, occasionally to the point of apnea. The chemical control of breathing depends no longer on the CO_2 -pH stimulus but on the stimulus of hypoxemia acting through the peripheral chemoreceptors. When hypoxemia is relieved, the stimulus for ventilation decreases and hypoventilation is accentuated.

The term carbon dioxide narcosis, frequently used to describe the above sequence of events, is misleading. No direct relationship exists between the absolute level of arterial CO_2 tension and either the cerebral symptoms or the hypoventilation. Severe hypoventilation may occur following oxygen administration to patients free of pulmonary disease with only modest initial elevations of CO_2 tension induced by narcotics. Also, some patients with marked elevations of CO_2 tension may show little or no central nervous system malfunction. The exact role of CO_2 in the pathogenesis of the syndrome remains to be elucidated.

Therapy of carbon dioxide narcosis should include measures which improve both the blood gas abnormalities and the mechanical abnormalities. Although oxygen administration in hypercapnic patients should be undertaken with great care, the question confronting the physician is not whether oxygen therapy is advisable but how to give oxygen without incurring additional hypoventilation. Relief of hypoxia must be a cardinal objective. If oxygen administration results in severe hypoventilation, assisted breathing is indicated. Bronchodilators, sputum liquefaction and removal, and the other measures designed to relieve pulmonary obstruction (p. 1573) are mandatory.

Abnormalities of neural or neuromuscular transmission to the respiratory muscles may result in paresis or paralysis leading to alveolar hypoventilation. Amyotrophic lateral sclerosis is an example

of an upper motor neuron lesion which may produce respiratory insufficiency. Direct involvement of the anterior horn cells by poliomyelitis virus represents a lower motor neuron lesion which produces respiratory insufficiency. Infectious neuritis (Guillain-Barré syndrome) produces flaccid paralysis by means of an inflammatory reaction involving ganglion cells and peripheral nerves. Myasthenia gravis produces respiratory failure by abnormalities involving the myoneural junction.

Direct involvement of respiratory muscles by diseases diffusely affecting skeletal muscle, like progressive muscular dystrophy and the myotonic dystrophies, may lead to restrictive disease. These diseases are commonly associated with reduction of vital capacity, total lung capacity, and maximal breathing capacity without obstructive disease.

The severity of respiratory involvement in any of the above diseases depends on the amount of anatomic involvement. Vital capacity is reduced in proportion to the degree of paresis of the respiratory muscles. There are generally an increased residual volume and a decreased air flow velocity. In moderately severe involvement, there may be alveolar hypoventilation with hypoxemia, hypercapnia, and respiratory acidosis. In very severe involvement, there may be total apnea requiring assisted ventilation for survival.

Because of ineffective coughing and the limitation of respiratory excursions, recurrent bronchial infection is frequent in the convalescing or chronically ill patient. Although none of these diseases is associated with parenchymal lung damage, per se, recurrent infections may result in permanent structural damage. In some patients, the neuromuscular or muscular disease may result in kyphoscoliosis, giving rise to additional pulmonocardiac abnormalities, as discussed below.

Recognition of pulmonary insufficiency may be difficult in the milder forms of these diseases. An awareness of the frequency of respiratory insufficiency is an important factor in formulating therapy. Quantitative serial measurements of vital capacity and blood gases are important guides as to the intensity of disease and the degree of therapy required. When relatively specific measures are available for a given disease (e.g., anticholinesterases for myasthenia gravis), they should be energetically employed. Assisted ventilation, control of secretions, and prompt therapy of infections are frequently critical aspects of the care of these patients.

Thoracic Cage Limitation. Limitation of motion of the thoracic cage may be associated with the development of severe alveolar hypoventilation. The mechanisms underlying this development may be illustrated by considering pulmonary-cardiac failure associated with kyphoscoliosis and with obesity.

delirium and even coma may occur. The electroencephalogram may show abnormalities consisting of slow-frequency, low-voltage waves. The combination of papilledema, central nervous system signs, and an abnormal electroencephalogram may lead to an erroneous diagnosis of brain tumor.

The combination of hypoxia and hypercapnia produces pulmonary hypertension and right heart failure by mechanisms discussed later (p. 1537). This form of cor pulmonale is characterized by its reversibility when blood gases are restored to normal.

The symptoms of alveolar hypoventilation are so varied that the diagnosis can be securely established only by demonstrating a significant increase of arterial or alveolar CO_2 tension.

Pulmonary restriction may result from abnormality of any segment of the respiratory apparatus. Disorders involving the respiratory center, its peripheral neural connections, the respiratory muscles, thoracic cage, pleura, mediastinum, pulmonary parenchyma (including its vasculature), and abdominal cavity may produce limitation of the respiratory stroke volume.

Restrictive Disease Associated with Neurologic, Neuromuscular, or Muscular Disorders. Restrictive disease may be produced by direct involvement of the medullary respiratory center by a number of different processes. The existence of hypoxemia, hypercapnia, and polycythemia in patients without clinical or physiologic evidence of primary respiratory or cardiac disease has been attributed to idiopathic disease of the medullary respiratory center. Such patients are capable of restoring blood gases to entirely normal values by voluntary hyperventilation. Meticulous investigation of pulmonary and cardiac function fails to reveal any abnormalities of ventilation, diffusion, or perfusion. Cardiac abnormalities, when present, are related to cor pulmonale produced by the blood gas abnormalities. Inhalations of high concentrations of CO_2 (5 to 8 per cent) in air by these patients fails to elicit the degree of hyperventilation seen in normal subjects or may even lead to depression of ventilation. For this reason, it has been suggested that the underlying mechanism is an injury involving the medullary respiratory center (such as tumor, inflammatory disease, or vascular accident) and resulting in relative insensitivity to its normal stimuli, P_{CO_2} and pH. Alveolar hypoventilation develops with resultant hypoxemia and hypercapnia. The chemical control of breathing depends to a great extent on impulses arising from the peripheral chemoreceptors located in apposition to the great vessels (carotid body, vertebral body, aortic body), which are primarily sensitive to a fall in the oxygen tension of arterial blood (hypoxemia). The volume of involuntary ventilation achieved by the patient represents a new steady state, which depends on the

degree of respiratory center depression and on the degree of respiratory stimulation arising from the peripheral chemoreceptors. This steady state operates in such a manner that the patient has persistent hypoxemia and hypercapnia.

A number of inflammatory and miscellaneous diseases involving the brain often may result in alveolar hypoventilation. For example, acute bulbar poliomyelitis causes respiratory abnormalities in the absence of respiratory muscle paresis or paralysis produced by lower motor neurone lesions. Breathing becomes irregular in rate, shallow, and exceedingly slow. It is striking that such patients can breathe normally when commanded to do so by frequent and firm verbal orders. The retention of volitional control with the loss of reflex rhythmic control is presumably caused by impaired sensitivity of the respiratory center to the CO_2 -pH stimulus. Not infrequently, swallowing and coughing are likewise impaired, again suggesting brain stem localization of disease. Generally this variety of respiratory disturbance is acute and transient, although the patient may then develop frank respiratory paralysis because of lower motor neurone disease.

A number of drugs are capable of producing respiratory center depression, thereby resulting in alveolar hypoventilation. Drug-induced respiratory depression is most frequently seen during administration of anesthesia. The reduction of ventilation is noted by the anesthesiologist and is treated by assisted ventilation. However, if specific measurements of alveolar or arterial CO_2 tension are not performed, significant hypoventilation, during or after the operative procedure, may be overlooked. All drugs of the morphine group and the barbiturate group may produce respiratory center depression and hypoventilation. With ordinary doses in patients without preexistent respiratory center depression, the respiratory effects of these drugs are ordinarily not of great clinical significance. However, overdosage (e.g., in attempted suicide) or the administration of even modest doses to patients with established respiratory depression may result in life-threatening alveolar hypoventilation.

An important variety of respiratory center depression is seen commonly in patients with prolonged hypercapnia, which occurs most commonly in obstructive emphysema. Such patients show a subnormal ventilatory response to the inhalation of CO_2 -enriched air. At least two basic factors are involved. One factor is related to the disordered ventilatory mechanics of diffuse obstructive disease. This factor can be demonstrated by having normal subjects inhale CO_2 -enriched mixtures while airway resistance is artificially increased. Under these circumstances there is a diminished ventilatory response to CO_2 inhalation. The second factor is

delirium and even coma may occur. The electroencephalogram may show abnormalities consisting of slow-frequency, low-voltage waves. The combination of papilledema, central nervous system signs, and an abnormal electroencephalogram may lead to an erroneous diagnosis of brain tumor.

The combination of hypoxia and hypercapnia produces pulmonary hypertension and right heart failure by mechanisms discussed later (p. 1537). This form of cor pulmonale is characterized by its reversibility when blood gases are restored to normal.

The symptoms of alveolar hypoventilation are so varied that the diagnosis can be securely established only by demonstrating a significant increase of arterial or alveolar CO_2 tension.

Pulmonary restriction may result from abnormality of any segment of the respiratory apparatus. Disorders involving the respiratory center, its peripheral neural connections, the respiratory muscles, thoracic cage, pleura, mediastinum, pulmonary parenchyma (including its vasculature), and abdominal cavity may produce limitation of the respiratory stroke volume.

Restrictive Disease Associated with Neurologic, Neuromuscular, or Muscular Disorders. Restrictive disease may be produced by direct involvement of the medullary respiratory center by a number of different processes. The existence of hypoxemia, hypercapnia, and polycythemia in patients without clinical or physiologic evidence of primary respiratory or cardiac disease has been attributed to idiopathic disease of the medullary respiratory center. Such patients are capable of restoring blood gases to entirely normal values by voluntary hyperventilation. Meticulous investigation of pulmonary and cardiac function fails to reveal any abnormalities of ventilation, diffusion, or perfusion. Cardiac abnormalities, when present, are related to cor pulmonale produced by the blood gas abnormalities. Inhalations of high concentrations of CO_2 (5 to 8 per cent) in air by these patients fails to elicit the degree of hyperventilation seen in normal subjects or may even lead to depression of ventilation. For this reason, it has been suggested that the underlying mechanism is an injury involving the medullary respiratory center (such as tumor, inflammatory disease, or vascular accident) and resulting in relative insensitivity to its normal stimuli, Pco_2 and pH. Alveolar hypoventilation develops with resultant hypoxemia and hypercapnia. The chemical control of breathing depends to a great extent on impulses arising from the peripheral chemoreceptors located in apposition to the great vessels (carotid body, vertebral body, aortic body), which are primarily sensitive to a fall in the oxygen tension of arterial blood (hypoxemia). The volume of involuntary ventilation achieved by the patient represents a new steady state, which depends on the

degree of respiratory center depression and on the degree of respiratory stimulation arising from the peripheral chemoreceptors. This steady state operates in such a manner that the patient has persistent hypoxemia and hypercapnia.

A number of inflammatory and miscellaneous diseases involving the brain often may result in alveolar hypoventilation. For example, acute bulbar poliomyelitis causes respiratory abnormalities in the absence of respiratory muscle paresis or paralysis produced by lower motor neurone lesions. Breathing becomes irregular in rate, shallow, and exceedingly slow. It is striking that such patients can breathe normally when commanded to do so by frequent and firm verbal orders. The retention of volitional control with the loss of reflex rhythmic control is presumably caused by impaired sensitivity of the respiratory center to the CO_2 -pH stimulus. Not infrequently, swallowing and coughing are likewise impaired, again suggesting brain stem localization of disease. Generally this variety of respiratory disturbance is acute and transient, although the patient may then develop frank respiratory paralysis because of lower motor neurone disease.

A number of drugs are capable of producing respiratory center depression, thereby resulting in alveolar hypoventilation. Drug-induced respiratory depression is most frequently seen during administration of anesthesia. The reduction of ventilation is noted by the anesthesiologist and is treated by assisted ventilation. However, if specific measurements of alveolar or arterial CO_2 tension are not performed, significant hypoventilation, during or after the operative procedure, may be overlooked. All drugs of the morphine group and the barbiturate group may produce respiratory center depression and hypoventilation. With ordinary doses in patients without preexistent respiratory center depression, the respiratory effects of these drugs are ordinarily not of great clinical significance. However, overdosage (e.g., in attempted suicide) or the administration of even modest doses to patients with established respiratory depression may result in life-threatening alveolar hypoventilation.

An important variety of respiratory center depression is seen commonly in patients with prolonged hypercapnia, which occurs most commonly in obstructive emphysema. Such patients show a subnormal ventilatory response to the inhalation of CO_2 -enriched air. At least two basic factors are involved. One factor is related to the disordered ventilatory mechanics of diffuse obstructive disease. This factor can be demonstrated by having normal subjects inhale CO_2 -enriched mixtures while airway resistance is artificially increased. Under these circumstances there is a diminished ventilatory response to CO_2 inhalation. The second factor is

kyphoscoliosis, is associated with an increased work cost of moving the thorax and is likewise associated with a tendency for the development of rapid, shallow breathing. A common pathogenetic mechanism responsible for the development of alveolar hypoventilation seems probable for both diseases. In the case of kyphoscoliosis, the increased work load is imposed by the thoracic deformity. In the case of the Pickwickian syndrome, the increased work load is imposed by the excessive deposition of fat. In Pickwickians, as in kyphoscoliosis, the increased work load leads to tachypnea with inadequate tidal volumes, which in turn leads to alveolar hypoventilation.

In the uncomplicated Pickwickian syndrome, there is no evidence of increased resistance to air flow. There is generally a decreased ventilatory response to CO_2 inhalation. This finding is consistent with a decrease in respiratory center sensitivity and tends to accentuate alveolar hypoventilation.

Intrapulmonary gas mixing may be entirely normal. Occasionally there is maldistribution of inspired air, presumably caused by the exaggeration of hypoventilation which occurs in the less distensible peripheral areas, producing ventilation-perfusion abnormalities and accentuating arterial oxygen unsaturation.

In occasional patients, the Pickwickian syndrome is associated with diffuse obstructive disease or myxedema. Pulmonary vascular occlusion, resulting from either embolism or thrombosis, is common. Its pathogenesis is undoubtedly related to the relative immobility of these patients, the high viscosity of their blood, and the presence of congestive failure.

Several clinical features of this syndrome require additional emphasis. Alveolar hypoventilation is relatively uncommon in even massively obese patients. Normal pulmonary function has been found in patients whose weight exceeded 400 lb. The exact factors which determine the development of pulmonary failure in some obese patients are not entirely understood. Among the factors favoring the development of alveolar hypoventilation are the pattern of distribution of the fat and its rate of accumulation. Pulmonary-cardiac failure occurs most commonly when the excess fat is packed tightly under the diaphragm, restricting its range of motion. Not infrequently there is a history of rapid weight gain in the immediate period preceding the development of frank pulmonary insufficiency. In some patients the rapid accumulation of intraabdominal fluid, rather than fat, may precipitate the full-blown syndrome.

The degree of somnolence is usually more severe in this syndrome than in other diseases associated with alveolar hypoventilation. At times the somno-

lence is truly extraordinary and the patient may find it impossible to distinguish between the waking and sleeping state. Somnolence occasionally antedates the appearance of respiratory insufficiency and may be present with only minor elevations of arterial CO_2 tension, suggesting the importance of independent central nervous system disease in the pathogenesis of the syndrome. Normal sleep is known to be associated with a rise in CO_2 tension and a decrease in respiratory center sensitivity. For this reason somnolence per se may increase the blood gas abnormalities.

The most remarkable aspect of both the clinical and physiologic abnormalities is that they may be completely reversed by simple loss of weight. With weight reduction, somnolence and the ventilatory abnormalities may disappear, blood gases may become normal, and pulmonary hypertension and cor pulmonale may disappear. Because of such dramatic changes, the Pickwickian syndrome represents an important example of curable lung and heart disease. However, in some patients, complicating obstructive pulmonary disease, independent heart disease, or pulmonary vascular occlusion limits reversibility.

The most important aspect of therapy is weight reduction. It is generally not necessary for the patient to lose weight to the predicted or "ideal" level. Often the loss of only 25 or 30 lb is sufficient to restore normal pulmonary function. However, excessive appetite is frequently a fundamental part of the illness (or of the patient's personality) and recurrent gain of weight is not uncommon.

Restrictive Diseases Rarely Associated with Alveolar Hypoventilation. A number of primary restrictive diseases are rarely or never associated with alveolar hypoventilation. Pulmonary collapse (atelectasis) and pleural fibrosis are discussed in Chap. 264. *Pectus excavatum* (funnel chest) is a congenital malformation consisting of a depression of the lower portion of the sternum and the adjacent costal cartilages. The depressed sternum may compress and restrict the lower portions of the lung or may produce restriction by distortion of the diaphragm. Restriction due to pleural fibrosis is limited to the areas of lung involved in fibrosis. Bilateral constrictive calcific fibrosis may result in virtually complete loss of thoracic motion and even limitation of diaphragmatic motion. Rheumatoid spondylitis has been shown to result in loss of chest expansion because of immobility of the costovertebral and costosternal joints. Reduction of vital capacity and total lung capacity with a normal residual volume result from this immobility. An interesting aspect of the impaired thoracic mobility is that painful or difficult sneezing is a common complaint. However, there is a striking absence of pulmonary signs and of pulmonary infections.

Pulmonary-cardiac Failure Associated with Kyphoscoliosis. Kyphosis refers to any posterior angulation of the spine. Clinically significant kyphosis is generally associated with a marked gibbus and loss of stature. Scoliosis consists of a lateral displacement of the spine with at least one other compensatory curve in an opposite direction. Of these two processes, scoliosis appears to be the more important in the genesis of pulmonary and/or cardiac insufficiency. Approximately 80 per cent of cases of kyphoscoliosis are of unknown etiology. The sequelae of poliomyelitis or of Pott's disease account for most of the remaining 20 per cent. Although kyphoscoliosis is relatively common (in approximately 1 per cent of the United States population), a deformity severe enough to produce pulmonary or cardiac insufficiency is found in only a relatively small number of these patients.

Kyphoscoliosis is associated with marked structural abnormality of the thoracic cage, leading to abnormal positioning and functioning of the respiratory muscles. The lungs are compressed by the thoracic deformity, leading to a small lung volume. There is a high work and energy cost of breathing, primarily because of the abnormal elastic resistance of the chest and, to a lesser degree, because of increased elastic resistance of the lung. In some unknown manner, the increased elastic work leads to the development of rapid shallow breathing, which in turn leads to alveolar hypoventilation by preferential ventilation of the anatomic dead space at the expense of the alveoli. As a result hypoxemia, hypercapnia, and respiratory acidosis develop. Prolonged hypercapnia leads to a depression of respiratory center sensitivity, accentuating the degree of hypoventilation.

The thoracic deformity leads to compression of pulmonary vessels which, therefore, present an increased resistance to pulmonary blood flow. With prolonged pulmonary hypertension, there is damage to the intima of pulmonary vessels with the development of pulmonary arteriosclerosis, which further increases pulmonary vascular resistance and aggravates pulmonary hypertension. The combination of hypoxia, hypercapnia, vascular compression, and intimal changes produces high degrees of pulmonary hypertension, leading ultimately to right ventricular failure.

It should be emphasized that the physiologic processes leading to alveolar hypoventilation in kyphoscoliosis are quite distinct from those seen in obstructive emphysema. In kyphoscoliosis, lung volumes are small; there are, at most, moderate disturbances in the distribution of inspired air, and air flow resistance is normal. In chronic obstructive emphysema (p. 1520), the residual volume is abnormally large, there are marked disturbances in the distribution of inspired air, and the major de-

fect is an abnormally high resistance to air flow.

Recurrent pulmonary infections are not uncommon in kyphoscoliosis because of abnormal cough dynamics and inadequate bronchial drainage. Such infections may lead to parenchymal pulmonary structural abnormalities and occasionally to obstructive emphysema. In such patients diffuse obstructive disease represents a complication superimposed on the fundamental physiologic abnormalities related to the thoracic deformity.

The therapy of pulmonary and cardiac failure in kyphoscoliosis should be directed toward correcting the physiologic abnormalities, since the underlying anatomic abnormality is unfortunately almost never correctible. The periodic use of mechanically assisted ventilation decreases the work cost of breathing and increases alveolar ventilation. Control of bronchial secretions and prompt therapy of pulmonary infections decrease parenchymal pulmonary destruction. Avoidance of drugs which depress ventilation prevents additional hypoxia and respiratory acidosis. Oxygen administration relieves hypoxia and tends to decrease the right ventricular work. Cardiac glycosides, diuretics, and a low sodium diet are useful in the management of congestive heart failure.

Pulmonary-cardiac Failure Associated with Obesity (Pickwickian Syndrome). The association of obesity, somnolence, polycythemia, and excessive appetite has long been recognized. A classic description of the association of these signs and symptoms was written by Charles Dickens. In "The Pickwick Papers," he described, "a fat and red-faced boy in a state of somnolency." The boy (Joe) was subsequently addressed as "Young Dropsy," "Young Opium Eater," and "Young Boa Constrictor," no doubt in reference to his obesity, his somnolence, and his excessive appetite, respectively. Because of the resemblance of Joe, the fat boy, to patients with obesity associated with pulmonary-cardiac failure, this combination has been referred to as a "Pickwickian syndrome."

In its fully developed form, the Pickwickian syndrome consists of marked obesity, somnolence, cyanosis, periodic respiration, secondary polycythemia, and right ventricular failure. Blood gas measurements reveal hypoxemia and hypercapnia, documenting the existence of alveolar hypoventilation. Measurements of lung volumes reveal a decrease of total lung capacity, a decrease of vital capacity, and a striking reduction of the expiratory reserve volume. The total energy cost of breathing in obese subjects is high. However the work cost of moving the lung is not increased. This suggests either that the excess energy is used to impart motion to extrapulmonary structures or that excess energy is required by the respiratory muscles to perform a given amount of mechanical work. Obesity, like

Pulmonary Scleroderma. Its general manifestations are described elsewhere (p. 1896). Pulmonary involvement in scleroderma is common. The manifestations vary depending on the site and extent of the disease. With extensive involvement of the skin of the thorax, there may be an inability to expand the chest adequately, leading to restrictive disease. Diffuse peribronchial fibrosis may lead to an obstructive pulmonary defect and to marked distortions of pulmonary parenchyma with the development of honeycombing of the lung. Pleural fibrosis may produce pulmonary restriction. Diffuse interstitial fibrosis may produce abnormalities of diffusion leading to the clinical and physiologic abnormalities of impaired diffusion which have already been described. With esophageal involvement, there may be "spillover" of esophageal contents, leading to recurrent bronchopneumonia. There may be direct involvement of the pulmonary vasculature by fibrosis, leading ultimately to the development of cor pulmonale. It has also been suggested that the proclivity of systemic vessels to show abnormal vasospasm may be shared by pulmonary vessels, thereby producing pulmonary hypertension and eventually cor pulmonale. Rarely, pulmonary manifestations may antedate the appearance of skin or esophageal lesions (scleroderma *sine* scleroderma). Under this circumstance, diagnosis is difficult since the histologic appearance of the pulmonary lesions is not specific. The coexistence of scleroderma and bronchiolar (alveolar cell) carcinoma occurs with sufficient frequency to suggest more than a coincidental relationship between the two diseases.

Diffuse Interstitial Fibroses and Granulomatoses of Unknown Etiology (Including Hamman-Rich Syndrome). Granulomatous and/or fibrotic involvement of pulmonary interstitium occurs in a number of disease states the etiologic nature of which is not well established. Obscure pulmonary infections, viral pneumonias, pulmonary venous occlusion and hypertension, and allergic reactions may all be associated with interstitial infiltration. Such infiltration may be localized or diffuse and may regress quickly or may persist indefinitely. When such infiltrates are extensive and persist for relatively long periods, the familiar clinical manifestations of diffusion abnormalities may appear. Despite exhaustive diagnostic studies, frequently no etiologic basis is found and only a descriptive pathologic diagnosis is possible. Of this indefinite group of entities, the best characterized is the Hamman-Rich syndrome. In 1935 and again in 1944, Hamman and Rich reported four patients with an unusual form of pneumonia characterized by progressive interstitial fibrosis of both lungs. The disease was accompanied by progressive hypoxia and the ultimate development of right ventricular failure. The disease in

each patient ended fatally within a year of onset. Since this original description a relatively large number of patients have been described who more or less fit into this diagnostic category.

The histologic abnormality consists of a bilateral, diffuse interstitial infiltrate resulting from the successive deposition of abnormal inflammatory cells, fibroblasts, hyaline, and collagen, in alveolar septums. Clinical features include dyspnea, cough, and cyanosis, terminating in many patients with intractable pulmonary insufficiency and cor pulmonale. Physiologically, there is evidence not only of abnormal diffusion but of abnormal ventilation-perfusion relations as well.

The etiology of this disorder is unknown and indeed it seems likely that a number of different processes may have as their end result the development of Hamman-Rich changes. Etiologic theories include viral infection with an unknown agent, infection caused by the pleuropneumonia group, the failure of resolution of acute interstitial pneumonia, a hypersensitivity reaction, and a form of collagen disease. Germane to the last two possibilities is that hypergammaglobulinemia, splenomegaly, and eosinophilia have been reported in some patients with Hamman-Rich syndrome.

The radiographic signs vary, and severe physiologic involvement has been reported in patients with only moderate x-ray abnormalities. The chest films in some patients resemble those found in congestive heart failure with marked cardiomegaly, and lung lesions resembling pulmonary edema; or the chest x-ray may resemble those found in diffuse bronchopneumonia; or the films may reveal diffuse interstitial fibrosis. Adrenal steroids apparently have induced remissions in some patients. Such remissions tend to be rather limited in time. Hormone withdrawal may produce a severe and unrelenting relapse.

Disorders of Impaired Diffusion Associated with Intraalveolar Fluid Accumulation and Relatively Normal Diffusing Membranes (Alveolar Block)

Pulmonary Edema. The general subject of pulmonary edema is discussed elsewhere (p. 1382). A priori, it might be expected that edema of interstitial tissue and edema fluid inside alveoli would tend to act as a diffusion barrier. Indeed, a decrease in diffusing capacity has been reported in some patients with pulmonary edema. However, a decrease in diffusing capacity is not found in all patients with pulmonary edema, nor does the decrease correlate well with the extent of pulmonary edema.

The major gas exchange abnormality in pulmonary edema appears to be based on rather complete exclusion of air from bubble-filled alveoli

Chronic pulmonary fibrosis and insufficiency may develop in the late stages of these disorders

Chronic Beryllium Disease of the Lung. The inhalation of certain salts of beryllium by human beings (p. 1547) leads to the development of pulmonary lesions. In the acute form of the disease there is the development of a chemical pneumonia, characterized by cough, with occasional blood-streaking of the sputum, substernal burning pain, dyspnea, cyanosis, anorexia with weight loss, progressive fatigue, and diffuse radiologic densities. In patients who recover, the lung fields generally clear after several months

Beryllium exposure is also capable of producing a chronic form of lung disease. This disorder develops insidiously months to years after the initial exposure. The clinical picture is that associated with diffusion defects. Pathologically the pulmonary lesions are indistinguishable from those seen in sarcoidosis, and indeed beryllium, like sarcoidosis, may be associated with granulomatous and fibrotic lesions involving lymph nodes, liver, spleen, and heart. Definitive diagnosis is generally based on a history of exposure to beryllium, together with suitable histologic changes on lung biopsy. The chemical demonstration of beryllium in lung or urine may help to reinforce the diagnosis. Therapy includes the use of adrenal steroids, oxygen, and measures designed to relieve cor pulmonale.

Asbestosis. The inhalation of asbestos dust (hydrated calcium-magnesium silicate) may lead to the development of a diffuse interstitial pulmonary fibrosis known as *asbestosis* (p. 1517). A striking feature of the reaction to asbestos is the development of marked pleural fibrosis. Significant physiologic derangements indicating abnormalities of diffusion have been noted even in the absence of x-ray changes.

Silicosis. Silicosis, the disease resulting from the inhalation of silicon dioxide dust, is described elsewhere (p. 1544). Usually this disease gives rise to an obstructive ventilatory defect whose end stage is chronic obstructive emphysema. Occasionally, patients with silicosis present with physiologic abnormalities consistent with impaired diffusion and without significant obstruction.

Lymphangitic Carcinomatosis. Lymphangitic carcinomatosis (see also p. 1562) may be defined as a process in which there are widespread neoplastic metastases throughout the lymphatics of both lungs. It differs from the more common varieties of pulmonary metastases in that it causes severer symptoms and is the direct cause of death in most patients

The primary tumor may arise from any site, but bronchogenic carcinoma and carcinoma of the stomach are the most common primary tumors. The primary tumor may be small and clinically in-

apparent during life. The outstanding symptom is severe and rapidly progressive dyspnea. The characteristic radiologic appearance is that of fine stringlike shadows distinct from vascular markings, stretching from the hila to the periphery of all lung zones. Rarely the chest x-ray may be normal despite severe dyspnea. The possibility of lymphangitic carcinomatosis should be considered in older patients with marked dyspnea for which no other cause can be determined.

Postirradiation Fibrosis of the Lung. Pulmonary fibrosis resulting from x-ray radiation of the lung is a somewhat uncommon but definite clinical entity. It occurs as a complication of radiation therapy directed against neoplasms of thoracic structures such as carcinoma of the breast, lung, or esophagus or pulmonary lymphoma. Ordinarily, pulmonary fibrosis following therapeutic radiation is insignificant. Occasionally, marked fibrosis and severe pulmonary insufficiency may result.

The reaction to x-ray occurs in two stages. The initial stage is the development of acute radiation pneumonitis. There is damage to alveolar cells and capillary endothelium, with resultant swelling and necrosis of the capillary endothelium. Fibroblastic proliferation occurs relatively early and is especially severe in alveolar walls. The late reaction is characterized by a vascular hyaline fibrosis with thickening of alveolar walls and septums. Peribronchial and perivascular fibrosis are also present.

The clinical picture is so variable that a typical syndrome cannot be defined. Most patients with localized fibrosis are entirely asymptomatic. In others, mild dyspnea and cough may be present for limited periods. In a small number of patients with extensive bilateral involvement, there may be high fever, severe dyspnea, hyperventilation, cyanosis, and progressive pulmonary insufficiency. Pulmonary function studies in these patients suggest that the major defect present is impaired membrane diffusion.

It has been claimed that adrenal steroids may cause marked symptomatic improvements in patients with severe forms of the disease and may be useful prophylactically.

Pulmonary Reticuloendotheliosis (Eosinophilic Granuloma, Hand-Schüller-Christian Disease, Letterer-Siwe Disease). Pulmonary involvement in these diseases produces a diffuse fibrosis associated with formation of multiple small cysts (honeycomb lungs). The clinical course varies. The occurrence of spontaneous pneumothorax is frequent. Diabetes insipidus or bone lesions are commonly associated findings. In severe forms, impaired diffusion is a major physiologic abnormality. Diagnosis in general depends on the presence of other stigmata of the disease as well as pulmonary involvement. Radiation and/or steroid therapy has been advocated.

the patient may expire either of pulmonary or of cardiac failure. However, even with advanced emphysema, complicated by failure of the right side of the heart, vigorous treatment will often result in remarkable improvement in a patient who at first appeared to be hopelessly ill (p. 1573).

Diagnosis. The chief problem is the separation from right ventricular hypertrophy or failure, due to pulmonary hypertension caused by mitral stenosis or by failure of the left ventricle. When congenital disorders can be excluded, the presence of the typical manifestations of anoxia, i.e., excessive fatigue, cyanosis, polycythemia, and clubbing of the fingers, constitutes strong evidence in favor of cor pulmonale as compared to other types of acquired heart disease. Other valuable guides are the history of long-standing cough, clinical or x-ray phenomena pointing toward emphysema, extensive infiltrative or fibrotic disease of the lungs, the relatively small heart, and the absence of clinical, electrocardiographic, and radiologic evidence of left ventricular hypertrophy. Carbon dioxide retention is the rule in patients with cor pulmonale due to emphysema or chest deformities but is usually absent when other conditions are responsible.

The arm-to-tongue circulation time is likely to be prolonged in both conditions, but the abnormality affects particularly the arm-to-lung time in the patient with cor pulmonale, who may have a normal lung-to-tongue time because the pulmonary vascular bed is not widened.

When pulmonary heart disease is caused by an infiltrative or fibrotic disorder, total vital capacity is likely to be more reduced for a given degree of dyspnea than in the case of an individual with pulmonary congestion due to left ventricular failure or to mitral stenosis. On the other hand, when emphysema or some other basically obstructive disorder is mainly responsible for cor pulmonale, the total vital capacity may be relatively high, even though the timed vital capacity and similar measurements are reduced as compared to comparably severe cardiac dyspnea secondary to pulmonary congestion.

The considerations which are important in the differentiation of cor pulmonale from those exceptional instances of mitral stenosis, in which a clear diastolic rumble is lacking, have been considered in some detail on p. 1438.

Pain resembling that of angina pectoris in its relation to exertion is not uncommon in patients with cor pulmonale. The duration may be much longer, and episodes lasting for several hours may occur and be confused with myocardial infarction. Although this type of pain responds poorly to nitroglycerin, it is probably related to ischemia of the right ventricle, induced by diminished systolic perfusion as the result of the abnormal elevation

of the intramural pressure in this chamber (p. 33).

Attacks of syncope are not unusual in patients with cor pulmonale and with the exception of heart block and aortic stenosis are more frequent than with other types of acquired cardiac disease.

In summary, it may be said that the diagnosis of cor pulmonale will usually depend on the demonstration of clear evidence of diffuse pulmonary disease in association with the signs of anoxia, of right ventricular hypertrophy, and of systemic congestion.

Treatment. The principles involved are (1) prevention and vigorous management of chronic and recurrent acute respiratory infections (p. 1576); (2) use of bronchodilator drugs, expectorants, steam inhalations (p. 1574), enzymes to thin sputum, and, under appropriate circumstances, of steroids; (3) management of anoxia and of hypercapnia, with due consideration of the dangers of aggravation of these disturbances by morphine and other respiratory depressants (p. 1575); (4) reduction of blood viscosity by venesection when the hematocrit is greater than 50 to 55 per cent; (5) management of congestive heart failure with digitalis and diuretics (p. 1586); and (6) utilization of mechanical aids to breathing when such adjuncts are needed (p. 1576). Each of these therapeutic problems is discussed in detail in other chapters, and especially in those concerned with pneumonia, respiratory failure, and congestive heart failure. There is some evidence that Isuprel, Priscoline, and rauwolfia derivatives may lower pulmonary vascular resistance.

of serotonin, and heparin is believed to be an antidote for this effect.

In certain tropical regions schistosomiasis with obstructive inflammation of the pulmonary vessels is a common cause of cor pulmonale. This disorder is occasionally seen in the United States in immigrants from Puerto Rico or other tropical regions.

Chest deformities may produce heart failure without significant parenchymal disease of the lungs. When there is extreme obesity, hypoventilation is the major factor (p. 1524). Kyphoscoliosis causes interference with gas exchange plus turbulent flow through distorted vessels.

There is a serious disorder known as "primary pulmonary hypertension" which is associated with increased resistance of unknown cause. Most of the patients are young women who have recently passed through pregnancy. Multiple embolism of the small pulmonary branches, possibly due to amniotic fluid, has been considered by some observers to be the responsible factor.

Passive congestion of the lungs also tends to elevate resistance. Aside from the mechanical increase of pulmonary capillary pressure due to left ventricular failure or to mitral stenosis, there is some evidence that congestion of one portion of the lung leads to reflex vasoconstriction in other areas. However, the quantitative significance of such a reflex effect is not established.

Increased pulmonary blood flow may result from anoxia, which thus has a doubly harmful effect because it also produces constriction of the arterioles. Acute respiratory infections not only may aggravate anoxia but also tend to increase cardiac output because of fever, tachycardia, emotional stress, and the elevation of metabolism incident to labored breathing.

Those congenital anomalies associated with large left-to-right shunts (p. 1423) may produce striking increase in blood flow through the lungs, and this in turn tends to lead to slowly progressive and eventually irreversible thickening of the smaller branches of the pulmonary arteries.

The precise quantitative significance of these several factors which increase pulmonary arterial pressure varies according to the type and severity of the underlying disease process.

Clinical Manifestations. The signs of the primary underlying disorder will naturally vary according to whether emphysema, infiltration of the lung, chest deformity, or extreme obesity (the Pickwickian syndrome) is responsible. In the absence of manifestations of some such underlying disorder, a patient presenting evidence of cor pulmonale should be subjected to the most careful search for some possible area of clinically silent venous thrombosis from which emboli might have arisen.

The second group of phenomena, which are characteristic of pulmonary heart disease, are the signs of right ventricular hypertrophy (p. 1406). This is commonly overlooked in the x-ray but will usually be made apparent by an exaggerated systolic lift of the precordium or of the epigastric area. Most of the patients exhibit a narrow spiked P wave in leads II and AVF (P pulmonale), and many of them display electrocardiographic signs of right ventricular hypertrophy.

The signs of anoxia are often pronounced. This cyanosis is more striking than in other patients with right ventricular failure, while clubbing of the fingers is relatively common, as contrasted to its rarity in patients with other types of acquired heart disease. Marked fatigability is usually present, and drowsiness is pronounced in the advanced stages.

A few of the patients exhibit the clinical phenomena of elevated cardiac output, with a wide pulse pressure, loud heart sounds, and exaggerated peripheral pulsations. These signs are most likely to be seen in the presence of anoxia or of fever and in patients with minimal or no signs of congestive failure.

The manifestations of right ventricular failure due to any one of this group of disorders are essentially the same as those due to other causes (p. 1381).

Natural History and Prognosis. The outlook depends on the cause and on the physiologic disturbances. When a reversible condition, such as prolonged severe asthma, is at fault, complete recovery may occur. Acute cor pulmonale due to a single massive embolus may likewise be followed by complete recovery if the patient survives the initial insult.

Regardless of the underlying cause, bronchial obstruction, infection, anoxia, and the increased blood viscosity due to polycythemia are partially reversible in most instances.

The subacute type of the disorder is most likely to occur when there is some rapidly progressive disease such as miliary carcinosis or tuberculosis, a spreading fungous infection, or progressive interstitial fibrosis. Unless the underlying cause is subject to therapeutic control, such patients usually expire within a few weeks.

Once right-sided failure has appeared as the result of primary pulmonary hypertension, the outlook is also grave. Such individuals rarely live for more than a year or two.

The most common clinical picture is that of chronic cor pulmonale due to bronchitis and emphysema. In these individuals heart failure occurs at first only when there is a complicating respiratory infection and improves as this is controlled. After some years of such an intermittent course,

the patient may expire either of pulmonary or of cardiac failure. However, even with advanced emphysema, complicated by failure of the right side of the heart, vigorous treatment will often result in remarkable improvement in a patient who at first appeared to be hopelessly ill (p. 1573).

Diagnosis. The chief problem is the separation from right ventricular hypertrophy or failure, due to pulmonary hypertension caused by mitral stenosis or by failure of the left ventricle. When congenital disorders can be excluded, the presence of the typical manifestations of anoxia, i.e., excessive fatigue, cyanosis, polycythemia, and clubbing of the fingers, constitutes strong evidence in favor of cor pulmonale as compared to other types of acquired heart disease. Other valuable guides are the history of long-standing cough, clinical or x-ray phenomena pointing toward emphysema, extensive infiltrative or fibrotic disease of the lungs, the relatively small heart, and the absence of clinical, electrocardiographic, and radiologic evidence of left ventricular hypertrophy. Carbon dioxide retention is the rule in patients with cor pulmonale due to emphysema or chest deformities but is usually absent when other conditions are responsible.

The arm-to-tongue circulation time is likely to be prolonged in both conditions, but the abnormality affects particularly the arm-to-lung time in the patient with cor pulmonale, who may have a normal lung-to-tongue time because the pulmonary vascular bed is not widened.

When pulmonary heart disease is caused by an infiltrative or fibrotic disorder, total vital capacity is likely to be more reduced for a given degree of dyspnea than in the case of an individual with pulmonary congestion due to left ventricular failure or to mitral stenosis. On the other hand, when emphysema or some other basically obstructive disorder is mainly responsible for cor pulmonale, the total vital capacity may be relatively high, even though the timed vital capacity and similar measurements are reduced as compared to comparably severe cardiac dyspnea secondary to pulmonary congestion.

The considerations which are important in the differentiation of cor pulmonale from those exceptional instances of mitral stenosis, in which a clear diastolic rumble is lacking, have been considered in some detail on p. 1438.

Pain resembling that of angina pectoris in its relation to exertion is not uncommon in patients with cor pulmonale. The duration may be much longer, and episodes lasting for several hours may occur and be confused with myocardial infarction. Although this type of pain responds poorly to nitroglycerin, it is probably related to ischemia of the right ventricle, induced by diminished systolic perfusion as the result of the abnormal elevation

of the intramural pressure in this chamber (p. 33).

Attacks of syncope are not unusual in patients with cor pulmonale and with the exception of heart block and aortic stenosis are more frequent than with other types of acquired cardiac disease.

In summary, it may be said that the diagnosis of cor pulmonale will usually depend on the demonstration of clear evidence of diffuse pulmonary disease in association with the signs of anoxia, of right ventricular hypertrophy, and of systemic congestion.

Treatment. The principles involved are (1) prevention and vigorous management of chronic and recurrent acute respiratory infections (p. 1576); (2) use of bronchodilator drugs, expectorants, steam inhalations (p. 1574), enzymes to thin sputum, and, under appropriate circumstances, of steroids; (3) management of anoxia and of hypercapnia, with due consideration of the dangers of aggravation of these disturbances by morphine and other respiratory depressants (p. 1575); (4) reduction of blood viscosity by venesection when the hematocrit is greater than 50 to 55 per cent; (5) management of congestive heart failure with digitalis and diuretics (p. 1586); and (6) utilization of mechanical aids to breathing when such adjuncts are needed (p. 1576). Each of these therapeutic problems is discussed in detail in other chapters, and especially in those concerned with pneumonia, respiratory failure, and congestive heart failure. There is some evidence that Isuprel, Priscoline, and rauwolfia derivatives may lower pulmonary vascular resistance.

263 PULMONARY DISORDERS DUE TO INHALATION OF NOXIOUS AGENTS

George W. Wright

AIR POLLUTION AND LUNG CLEANSING

That the air environment of specific work places may constitute a potential health hazard has long been recognized. The health hazard posed by urban air pollution and airborne infection has become a matter of increasing concern because of changing industrial practice, augmented use of petroleum products, and an increasing population density. Chronic bronchitis in England has been shown to be more common in urban than rural populations and far more common over all than in countries where home heating and industry cast fewer solids into the air. Cancer of the lung is statistically linked with population density and "air pollution." An augmented population density brings with it an increased discharge of incompletely burned automobile as well as home heating fuels and an increase in the number of persons exposed. The fumes of burning cigarette tobacco, an intense form of local air pollution, is linked statistically as a cause with both lung cancer and chronic bronchitis. The incidence and spread of airborne infection have been shown to be related to population density. Information regarding these extremely complex problems is meager and daily leads to conflicts of interest based on misinformation by both the laity and physicians. In spite of our comparative ignorance concerning important details of these problems, some valid information does exist which is of practical use to the physician in evaluating these health hazards.

Three facts explain why we survive so well under circumstances which, on superficial examination, one would think should cause grave consequences. The first of these is that, because of certain physical characteristics of airborne particulates, many never have an opportunity to enter the respiratory orifices or penetrate into the deeper parts of the lung. Secondly, the body possesses a remarkable ability to rid itself rapidly of particles deposited within the respiratory system. Third,

many things that are inhaled are biologically inert.

Particles discharged into still air will settle out with a speed dependent upon diameter, shape, and density. For example, quartz particles 200, 50, and 10 μ in diameter have a terminal settling velocity of 100, 20, and 0.5 cm per sec, respectively. It is apparent, therefore, that only particles of a size smaller than 10 μ stay suspended long enough to move very far from their points of origin. The bulk of heavy, visible industrial dusts are larger than 20 μ in diameter and settle out rapidly. Of great importance is the fact that particles smaller than 0.3 μ in diameter tend to remain permanently airborne. Smokes are generally in this latter class. Particles larger than 0.3 μ in diameter move only by virtue of motion of the air in which they are suspended, whereas those smaller than this tend to diffuse like gases. Because air is virtually never "still," there is constant mixing with progressive dilutions of contaminated by uncontaminated air. It is obvious that polluted air is being constantly changed in its character so that the farther one is from the source of contamination, the smaller and the fewer the particles in the air will be.

Of the particles present in the air entering the nose, those larger than 10 μ are almost completely removed along with 10 to 20 per cent of the smaller particles (down to a fraction of a micron) during transit from the nasal orifice to the larynx. The deposition within the nasopharynx occurs by reason of the effects of gravity, direct impingement, and to some degree, electrostatic precipitation. Particles smaller than 10 μ penetrate the larynx, but of these the larger ones are deposited on the surface of the bronchial system, with the net effect that 80 per cent or more of all particles larger than 3 μ are deposited in the upper respiratory tract. The smaller the size of the particle, the farther it tends to penetrate the air passages. Those larger than 5 μ penetrate deeply only in small numbers, while those smaller than 1 μ make up the majority of those penetrating farthest and in largest numbers.

Mass movement of air probably does not extend to the alveoli, and perhaps not even to the respiratory bronchioles. This means that practically all the deposited particulates larger than 0.3 μ fall on the mucociliary apparatus of the nose, pharynx, and tracheobronchial system. This remarkable apparatus comprises the surface of the area from the respiratory bronchioles up to and from the nasal orifice down to the oral pharynx. There is a constant movement of the mucous escalator toward the oral pharynx at a speed such that particles deposited anywhere on that surface reach the oral pharynx in less than 30 min. The material brought to the oral pharynx is either swallowed or expectorated.

Some particles of all sizes do reach the alveoli and nonciliated air tubes, though the majority are less than $3\ \mu$ in diameter. The effects of gravity on larger particles and diffusion of submicroscopic particles account for this deposit. What is their fate? Most, and perhaps all, are ultimately phagocytized by macrophages. Recent studies indicate that the majority are soon engulfed, and the loaded macrophages then move out onto the mucociliary escalator where they are subsequently disposed of. This process takes days rather than minutes. Some of the loaded macrophages apparently move into the interstitial tissues of the lung and thence via the lymphatics to the regional and more distal nodes of the lymphoid tissue or even into the blood stream. This process takes months. Naked particles can be seen upon the alveolar surface and in the interstitial tissue, a fact that has led some to believe that these particles move through the alveolar membrane by purely mechanical forces. It has been shown that particles taken up by macrophages may be discharged from or left behind by death of the macrophage only to be taken up again. This seems a more reasonable explanation of the naked particles seen within the interstitial tissues.

The clearance of particulates from the lungs has been extensively studied by using radioactive materials. The time course of removal of inhaled particles indicated above has been confirmed. As would be expected, on the basis of the preceding discussion, particles larger than $1\ \mu$ are almost completely removed in hours, smaller particles in days, and there is a small residuum that remains permanently.

Thus far, the fate of inanimate particulates has been discussed. What about living particulates? Evidence in this regard is meager. Fungi, bacteria, and viruses can become directly airborne by sneezing, coughing, and other subtle ways of creating aerosols. The individual droplets making up liquid aerosols are rapidly dehydrated, leaving behind droplet nuclei composed of the organisms and proteinaceous material. The size of these airborne droplet nuclei varies between 0.1 and $30\ \mu$. These could be expected readily to penetrate into the sublingual parts of the respiratory tract. Considering the number of persons who sneeze and cough and contaminate the atmosphere with respirable sized particles, why are the deeper parts of our lung sterile and why is transmission of infection relatively infrequent except under certain circumstances? Infection depends upon the number of viable organisms inhaled, the duration of residence within the body thus permitting time for propagation, and the favorableness of the environment where the organisms are deposited. These are complex factors, especially the third one. Organisms suspended in the relatively unfavorable environ-

ment of ambient air show great variation of viability; spores live a long time, but some bacteria survive less than a minute. The number of living organisms in the inhaled air will, therefore, be highly dependent on the proximity of the inhaler to the dispenser. Hence, crowding of populations is a prime factor in airborne spread of disease. Since many droplet nuclei are larger than $1\ \mu$, the majority will fall on the mucociliary escalator and be removed too quickly to permit colonization. Because of macrophage activity, plus mechanisms of immunity and perhaps direct antibacterial substances such as lysozyme, the human respiratory tract presents an adverse environment for propagation of living particulates.

The ability of the lung to cleanse itself is maintained at a high level of efficiency in normal persons. Precise quantitative data relating total deposition to permanent retention are not available. Analysis of the lungs of hard rock miners after more than 30 years of work usually reveals no more than 5 Gm of silicon dioxide as having been retained in the total lung tissue. On the basis of reasonable calculations, it can be assumed that such workers may have inhaled 500 Gm or more of silicon dioxide during this entire period. An upper limit of permanent retention of approximately 1 per cent seems reasonable but may be in considerable error. In any event, it gives a rough estimate of the effectiveness of the cleansing mechanism under circumstances of rather high loading.

If the cleansing capacity of the lung is so great, one can properly ask why it is that disease ever develops. That the inhalation of biologically inert materials fails to cause disease is easy to understand in the light of the fact that the material is inert and so little is retained over many years of exposure. It seems reasonable to assume, however, that whenever biologically active particulates of either inanimate or animate materials can accumulate in sufficient quantities in the lung, disease will ensue. Two factors are thus important. The first is that the materials must be biologically active, and second, a sufficient quantity must either be retained in the lung or be permitted to grow in the lung. The following factors are known to favor accumulation of particulates in the lung. Overloading doubtless plays a major role. A strong relationship between intensity and duration of exposure and subsequent disease has been repeatedly shown in numerous different circumstances. The corollary of this is that a load considered tolerable for a normal may be intolerable for a subnormal cleansing mechanism. Anything known to interfere with the effectiveness of the mucociliary apparatus or of the macrophage system or of immune reactions could hence be expected to favor the development of disease. Cigarette smoke, sulfur dioxide, nitrogen

dioxide, drying, and numerous other agents are known to impair mucociliary action. When these factors coexist in the inspired air with known injurious particulates such as silicon dioxide or carcinogenic hydrocarbons, the intensity-duration relationship must be augmented. Other factors undoubtedly play a role. For example, the virus of influenza is known directly to injure and destroy the cells of the tracheal mucosa, leaving such tissue vulnerable to infestation and infection by bacteria. Infection, either bacterial or viral, established in the supralaryngeal regions leads to copious production of secretions of a mucous and serous nature. These secretions are apt to be loaded with viable organisms. Normally, swallowing or expectoration disposes of these secretions. When, however, the pharynx is painful and swallowing is impaired or when drugs or sleep reduce the swallowing reflex, these bacteria-laden materials may often be, and often are, aspirated into the trachea and bronchi. The consequent introduction of viable organisms in a liquid medium may rapidly overload and impair the sublingual mucociliary escalator and promote the development of pneumonia or acute bronchitis.

The degree to which permanent impairment of lung cleansing might follow acute inflammatory disease of the tracheobronchial system is not clearly known. Acute pneumonias caused by the pneumococcus do not appear to be followed by such impairment. The same can be said to be generally true for chemical pneumonias. The ability of the respiratory apparatus to regenerate normal functioning tissues after repeated acute injury is probably great.

TYPES OF RESPONSE

For centuries it has been recognized that certain particulate substances cause no untoward effects even when inhaled for many years, whereas others may rapidly or gradually cause pulmonary changes that vary considerably in degree of severity and seriousness. The number of known pathogenic substances continues to increase with the recognition of previously obscured relationships and with the development of new substances or new situations to which men may be exposed.

The body response to these noxious agents is of two broad categories, acute pneumonitis and chronic granuloma with fibrosis. The acute response may be immediate or delayed hours or even days after the contact; in the chronic form there is, with one exception, a history of prolonged exposure and a delay in development of the body reaction. Because of the trend toward a delayed reaction, the inciting cause may be difficult to discover except

by the most painstaking anamnesis. In no other category of disease is the past history more important and at the same time apt to be so poorly explored. Most physicians have little contact with and knowledge of specific working conditions in industry and, hence, they are likely to be ill prepared to take an occupational history. No occupational history is adequate until the activities and surroundings of the patient during every year of his life are accounted for and the potential for hazard of each specific occupation is known.

Acute Reactions. The acute pulmonary injuries usually arise from the inhalation of irritant, vesicatory, or necrotizing gases or fumes. Certain gases have an immediate powerful irritating action which is characterized by lachrymation, burning and pain of the nose, pharynx, and trachea, and by severe cough. Strong concentrations may cause such severe irritation as to bring about prompt cessation of respiration, allegedly by laryngeal spasm. If the subject survives the immediate effects of the gas, pulmonary edema may ensue with subsequent recovery, or death may occur in spite of all efforts to provide relief. Other gases, for example, the nitrous fumes of detonated blasting powder or burning celluloid, may not cause such severe immediate reactions as to be unduly alarming, but after a delay of several hours, the patient may rather rapidly develop severe respiratory distress, cyanosis, and shock, with all the signs of pulmonary edema and exudate. Because serious delayed reaction is possible, it is wise to keep all persons who have been exposed to unusual concentrations of the irritating gases under close scrutiny for at least 24 hr. Some degree of inflammation and necrosis of tissue always occurs following severe pulmonary reactions, and during this period, the lungs are unusually susceptible to bacterial infection. Recovery may occur by resolution of the edema and inflammatory products or by fibrous replacement. Commonly there are no recognizable residues or sequelae.

That certain gases act primarily on the upper respiratory tract, whereas others affect chiefly the deeper structures of the lung, is partly attributable to their varying solubility in water. Ammonia, formaldehyde, hydrofluoric and hydrochloric acid are so soluble as to attack the first moist surface with which contact is made. The concentration of these chemicals in the air going to the deep parts of the lung is thus reduced to some extent on the way through the upper passages, and pulmonary injury is lessened. In contrast, nitrogen dioxide (nitrous fume), phosgene, and cadmium oxide fumes are relatively less soluble and hence less irritating to the upper respiratory tract. They can be respired without great discomfort and reach the deeper parts of the lung in atmospheric concentration that

may be exceedingly injurious. The reaction to these chemicals is delayed but often far more serious than that to those causing more immediate discomfort. In fact, the lack of distress immediately upon inhalation makes these gases especially dangerous. Midway between these two groups in solubility and action are sulfur dioxide, the halogens, and hydrogen sulfide.

Treatment of the acute reaction depends little or not at all upon the recognition of the specific noxious agent responsible for the event. Therapy is directed first at overcoming the alterations of physiology. Shock must often be combated. Oxygen in concentrations of 50 per cent or more is imperative. There is little scientific support for the use of positive pressure by mask although *a priori* reasoning has prompted its use. Practical experience has shown that physical struggle and unrest may cause sudden death. If positive pressure during inspiration makes breathing less of an effort and is tolerated without restlessness, it is not contraindicated except in shock. In the hypotensive state due to poor venous return, positive pressure breathing is contraindicated. The use of agents which lower the surface tension of serum might be useful when administered via the airway as recommended in pulmonary edema of circulatory origin, but the author has no information on this point. Sedation is very important. Bromides appear to be preferable to barbiturates. Morphine is contraindicated. The prophylactic use of antibacterials is recommended throughout the period of pulmonary inflammation.

Other relatively acute reactions of the lung to inhaled material are noteworthy because of the long delay between initial contact and the reaction. Although exposure to high concentrations of a fume thought to be anhydrous beryllium sulfate may cause a violent chemical pneumonitis in a few to 72 hr, a much more insidious chemical pneumonia (not to be confused with the chronic granuloma discussed later) is also known to occur in the beryllium extraction industry and in other exposures where beryllium fluoride and beryllium oxide are inhaled. In this reaction, which develops weeks or even months after exposure begins, the symptoms of dyspnea on exertion, paroxysmal cough, substernal pain, weakness, and weight loss may precede the development of any abnormal shadows seen in the roentgenogram of the chest by 1 to 3 weeks. When abnormal shadows develop, they are characterized by a granular haziness of a diffuse patchy distribution which, in some instances, may be fluffy in appearance. The pathologic change is that of a true chemical pneumonia. Treatment is the same as for the acute reactions described before. This disease is apt to persist for several weeks, and treatment must be continued throughout. The

use of ACTH or cortisone has not received adequate trial but should be explored. Recovery is the rule, but fatalities do occur.

A rather rare disease brought about by the inhalation of bagasse dust has been described in workers preparing bagasse from sugar cane or using it in manufacture. The true etiologic factor is unknown, but its association with bagasse seems established, and for the present, the disease might be properly included under the heading of this chapter. Weeks to months after the beginning of exposure to bagasse dust, the disease makes its presence known by severe paroxysmal cough and dyspnea. Fever may persist for weeks or months. The lung shows evidence of resistance to expansion. Cyanosis may be present. The white blood count is elevated, the polymorphonuclear cells forming 70 to 90 per cent of the total. The clinical picture is that of a diffuse pneumonia which persists for weeks. The scant tissue available for study shows an interstitial fibroelastic reaction. The pulmonary roentgenogram shows an abnormal diffuse pattern of fine stippling. Recovery is slow but usually occurs, and few if any sequelae remain. Treatment is symptomatic. The use of ACTH or cortisone has not been reported.

Chronic Reactions. As mentioned earlier, the majority of the various kinds of material inhaled and deposited in the lung cause no tissue reaction. Particles larger than $10\ \mu$ in size are not found in the deeper parts of the lung, but those of smaller size do reach the alveoli where they are engulfed by phagocytes. Soluble particles such as marble or gypsum disappear entirely, while those less soluble or insoluble particles are carried by the phagocytes to the lymphoid collection of the lung and mediastinum and there deposited. Many of the insoluble varieties of dust are inert so far as tissue reaction is concerned and do not cause significant fibrosis. The particles of such substances as iron, soot, etc., simply remain in the lymphoid tissue along the course of the lymphatic and blood vessels that accompany the bronchial tree. If present in large enough quantities, these inert substances may stimulate sufficient proliferation of fibrous tissue along the lymphatic channels to cause the shadows cast by normal pulmonary vascular markings to be exaggerated as to size, density, and projection toward the periphery. Indeed if the inert material is dense enough—as is iron, for example—the concentrated metallic deposits may themselves cause a shadow easily seen in the roentgenogram. Although these inert substances do cause a slight proliferation of fibrous tissue in their immediate vicinity, the reaction is mild, and there do not appear to be any recognizable evidences of interference with either the physiologic or immunologic functions of the respiratory apparatus from their retention. In

contrast to these so-called "inert" particulate substances, there are others which when inhaled cause definite tissue reaction.

PNEUMOCONIOSIS

Pneumoconiosis is a generic term embracing all chronic changes in the lung induced by the prolonged inhalation of dust of a nonliving character, with no implication as to the type or severity of the change. This definition is so broad that the term no longer connotes disease. The necessity for some such term is obvious when one realizes that only a few of the inhalable substances truly cause a pulmonary change that results in sufficient dysfunction to warrant the appellation of disease. The pneumoconioses of importance to health are silicosis, asbestosis, coal worker's pneumoconiosis (South Wales), pulmonary granulomatosis of beryllium workers, Shaver's disease, and diatomaceous earth pneumoconiosis. Of these, silicosis, asbestosis, and coal worker's pneumoconiosis (South Wales) have broad socioeconomic implications in addition.

Siderosis. Siderosis, one of the pneumoconioses generally termed benign because it has no demonstrable significance as regards health, nevertheless has definite economic implications because its pulmonary radiographic appearance mimics simple silicosis. Since it may occur in conjunction with industries which also are known to produce silicosis, the differential diagnosis is of considerable importance. A detailed history indicating heavy exposure to inhalation of iron oxide rather than free crystalline silica will usually establish the diagnosis. When pulmonary nodulation develops in a person who has done welding, oxyacetylene cutting of iron, or mining of hematite in atmospheres heavily contaminated with crystalline silica particles, the differential diagnosis may require lung biopsy.

Silicosis. Silicosis is a disease of the lungs caused by the prolonged inhalation of fine particles (less than 5μ) of free crystalline silica (SiO_2) in quantities sufficient to produce the characteristic fibrosis. It is manifested clinically by the development of discrete nodules confined to the lung and lymph nodes of the mediastinum, by an increased susceptibility to tuberculosis, and by a paucity of symptoms and signs during the discrete nodular phase of the disease. Severe evidences of respiratory embarrassment are likely to develop when conglomerate masses and secondary emphysema develop in the lungs.

With the exception of asbestos, the various silicates and amorphous silicas produce little or no reaction in the lungs. Silicosis, therefore, is associated only with those pursuits which expose one to the inhalation of naturally occurring or artificially produced forms of free crystalline silica. The common form of free silica is quartz, which is

abundantly distributed in the earth's surface. Mining, tunneling, rock-cutting, sandblasting, abrasive manufacture and use, ceramic manufacture, foundry work, and glass manufacture are among those industries associated in certain jobs with the production or handling of finely divided free crystalline silica. Not all jobs or locations in these industries expose the worker to hazardous quantities of silica. For example, coremakers in most foundries have little exposure to silica, whereas the sand reconconditioner or shake-out operator may have considerable. If, however, the coremaker works in a common room he may be exposed to an adjacent silica hazard. One can readily understand that an occupational history disclosing only that the occupation was miner or foundryman is entirely inadequate. Intimate knowledge of the job, working place, duration of various jobs, and even the actual place in which the work is done is an absolute necessity. Anything less provides inadequate data on which to evaluate the exposure of a given individual.

The silica particles that enter the alveoli and respiratory bronchioles are 10μ or under. Most visible dusts are made up of particles larger than this. It has also been shown that silica particles between 5 and 10μ act only as a foreign body and that the active or fibrogenic component of hazardous silica dust is 1 to 5μ . Many extremely "dusty" atmospheres as tested visually are really quite harmless so far as the lung is concerned. The reverse may be equally true, some very harmful exposures being where there is little visible dust. The occupational history must therefore elicit information about particle size as well as about the chemical nature of the dust.

It has been amply demonstrated that the total number of particles of hazardous size inhaled is an important consideration in determining the severity of pulmonary injury. Contrary to popular belief, the black native labor of the South African gold fields has a relatively low incidence of silicosis. This is thought to be attributable to the fact that the individual usually works only 9 to 18 months underground. The whites working in the same areas have a much higher incidence because they are employed on a long-term basis.

It is obvious from these considerations that the size and concentrations of hazardous particles and the duration of exposure are important determinants of whether or not silicosis will develop in a given individual. There is also a factor of individual variation that is related to the effectiveness of the individual's "air filter" and lung-cleansing mechanism. There is acceptable experimental and clinical evidence to show that, when the reticulo-endothelial system of the lung is saturated with inert foreign material, less than the usual amounts

of silica will produce silicosis. This has an obvious practical implication.

Experience has shown that dusts containing fewer than 5 million particles of free silica $10\ \mu$ or less in size per cubic foot will rarely cause silicosis in the normal working span of a man. Concentrations above 100 million are considered very unsafe for more than a few months of exposure. Under most working conditions of the past, it took 10 to 20 years of exposure to produce recognizable silicosis. Exceptional circumstances have been reported where unusual exposures of 2 or 3 years' duration produced the disease. Men exposed approximately a year to high concentrations of virtually pure silica develop a nonnodular change having more the appearance of a chemical pneumonia.

In most occupations, the inhaled dusts are a mixture of silica and other substances. There is no doubt that these accompanying dusts, as for example gypsum or iron, are capable of modifying the activity of the silica in such a way as to diminish and delay its fibrogenic action. In the experimental animal, finely divided aluminum hydrate and "metallic" aluminum have both been shown capable of so modifying the action of silica as to prevent the development of significant fibrosis.

After the silica particles reach the alveoli, they are picked up by phagocytes. These migratory cells carry their engulfed particles to regional lymphoid clusters and to the large nodes of the hilum and mediastinum. The actual process whereby the silica particles stimulate cell proliferation and fibrosis is unknown but appears to be a physicochemical process associated with surface phenomena. In the areas where the particles accumulate, fibroblastic proliferation and hyaline formation produce nodules of a characteristic whorled appearance. At first these silicotic nodules are found only in the larger lymph nodes; but as lymph drainage becomes progressively more impaired, the particles accumulate in the peripheral lymph channels along the course of the blood vessels, especially those of the pulmonary artery. The tissue reaction in these areas gives the vessels a beaded appearance which can be recognized in a pulmonary roentgenogram but not differentiated from the beading caused by dusts which are entirely free of silica. As more and more silica is accumulated in the periphery of the lung, the tissue reaction increases to form nodules which alone or by merging with other nodules achieve a size and density sufficient to cast a shadow on the roentgenogram. Reconstruction of the nodules in man has demonstrated that they usually form around, compress, and finally close off a blood vessel of the pulmonary artery tree. Around each nodule there is a zone of dilated air spaces described as focal emphysema. At this stage the

nodules are discrete and comprise a relatively small amount of the total lung tissue. The lung between the nodules has a normal appearance. This stage of silicosis has been categorized as simple discrete nodular silicosis. Some subdivide this group on the basis of the size of the nodules seen in the roentgenogram.

In many individuals, the reaction does not progress beyond the discrete nodular stage. In others, large irregular masses of very dense fibrous tissue with irregular radiating strands develop. As a rule this occurs in the upper parts of both lungs. In advanced stages the entire upper part of both lungs may be a dense shrunken mass of fibrous tissue firmly adherent to the chest wall, with the lower parts of the lung the site of severe diffuse emphysema. In some instances, it appears that these masses form by a shrinking together of the lung and conglomeration of the nodules. In others, there is little shrinkage but rather an extraordinary proliferation of fibrous tissue. When massive or conglomerate shadows appear in the roentgenogram, the disease is categorized as complicated or *conglomerate silicosis*. Rarely the conglomerate form appears with little or no discoverable accompanying discrete nodulation.

Histologic study reveals that, in 60 to 70 per cent of those persons exhibiting the conglomerate form of silicosis, evidences of tuberculosis can be found associated with the pulmonary masses. In the remainder, nontuberculous infection may have played a role in causing the intense proliferation of fibrous tissue. It seems logical to believe that previous nontuberculous infection may so damage the self-cleansing mechanism of the lung that unusual amounts of silica are likely to be retained at the site of previous infections and thus cause unusual fibrotic response in these areas.

The diagnosis of silicosis requires that one see nodulation characteristically distributed throughout the lungs in the roentgenogram, that other causes of the nodular pattern be ruled out, and that a history of exposure to the inhalation of free crystalline silica of particle size and amount capable of causing the nodular fibrosis be obtained. These requirements may seem unduly strict in view of the fact that a histologic stage of the disease must precede the clinical manifestations. The tendency to make a diagnosis of silicosis solely on the basis of a history of exposure to silica is certainly not realistic, because in actual practice the majority of persons so exposed never develop clinically significant evidences of the disease. To make the diagnosis on the basis of a positive occupational history and the presence or development of exaggerated bronchovascular shadows will lead to frequent false diagnoses. Many persons who have inhaled non-silica dust and some with no history of any dust

exposure at all will be found to have markedly exaggerated bronchovascular markings. To require nodulation demonstrable by roentgenogram in order to establish a diagnosis is justifiable both from a medicolegal point of view and from that of the person's health since no clinical significance is attached to the prenodular stage of silicosis.

In the simple discrete nodular stage of silicosis there are few related symptoms. Numerous investigators studying silicotic persons from several industries have found only slight evidences of impaired cardiorespiratory function. Many silicotics show entirely normal measurements during this stage. In others there is a moderate reduction of maximal breathing capacity and an absolute increase of residual air. These findings are evidence of slight diffuse obstructive emphysema. When conglomerate masses develop, these evidences of emphysema are likely to become more severe and may lead to complete respiratory crippling. In the simple discrete nodular stage there is no impairment of gas diffusion between the atmosphere and pulmonary blood. In the conglomerate stage, poor mixing and distribution associated with emphysema lead to a lowered alveolar pO_2 , and some degree of arterial hypoxia may develop during exercise. The physiologic abnormalities of conglomerate silicosis are caused primarily by the diffuse obstructive emphysema which accompanies this stage of silicosis. The complaint of exertional dyspnea is due almost entirely to a reduction in the ability to pump air into and out of the lungs. At this stage the clinical symptoms in addition to dyspnea on exertion are cough, expectoration, chest pain, and weakness. Cor pulmonale is a late complication and is the cause of death in many instances.

Discrete nodular silicosis appears to be progressive for a year or two after the individual is removed from exposure but then stabilizes, and life expectancy appears normal. The conglomerate form progresses slowly even after removal from exposure, and life expectancy is diminished.

Tuberculosis is the most feared complication of silicosis. Some individuals having simple discrete nodular silicosis may develop active tuberculosis, the characteristic infiltrates or cavities going through the conventional pattern that eventuates in subsequent spontaneous healing. This combination is best referred to as silicosis with tuberculosis and is reported to respond favorably to antibacterial therapy for tuberculosis. More often than not, however, active tuberculosis is prone to pursue one of three courses in the person with silicosis. In the unusual circumstance of a primary or hematogenous infection occurring in lungs already the site of silicosis, one finds that the peripheral zone of the silicotic nodule is a preferred site for the development of the tuberculous lesion. Previously sharp

borders of the shadow of the nodule in a roentgenogram become blurred, and the nodule enlarges. The tuberculous process proceeds with enhanced speed and practically always ends fatally. Reactivation of a preexisting tuberculous focus or the occurrence of exogenous reinfection may lead to rapidly developing cavitation. The disease may then become widely disseminated and will run a rampant and fatal course. In these two types of reaction, the tuberculosis is the most prominent feature. Spontaneous recovery is so unusual and the clinical course so adverse that this modification of tuberculous warrants the designation of silicotuberculosis.

A third combination occurs when silicosis and tuberculosis exist together in such a way as to produce massive fibrosis. The presence of conglomerate shadows in the silicotic person is assumed on statistical grounds to indicate complicating tuberculosis, although tuberculosis can be proved in only about 70 per cent of the cases. The silicosis and tuberculosis both are modified to the extent that they produce massive fibrotic conglomerates in which silicotic nodules and the granuloma of tuberculosis can be recognized histologically. Clinically the tuberculosis is modified by becoming very indolent and losing all or most of its invasive and disseminating character. This combination is termed tuberculosilicosis and can exist for many years with few if any symptoms other than cough and dyspnea on exertion.

Anthracosilicosis is a variant caused by the inhalation of a mixture of coal dust and free crystalline silica. In essence its course is very similar to conventional silicosis. It appears that emphysema may develop earlier and be more of a complication in the simple discrete nodular phase in anthracosilicosis.

The type of pathologic process which characterizes silicosis affords little hope of any form of effective treatment for the patient having well-established disease. Prevention by adequate control of all dust hazards is the answer to the problem. Aluminum powder has definite prophylactic action in animals, and presumably would also be effective in human beings unavoidably exposed to silica. No critical data on this point are available. Aluminum by inhalation has been recommended and tried as an agent to relieve the symptoms of silicosis. Critical data fail to support its effectiveness except as a form of psychotherapy. When active tuberculosis is a complication, antimicrobial therapy may be effective in the discrete nodular stage but has little if any influence on the massive conglomerate stage. Experience suggests that in the simple discrete nodular stage continued employment is well tolerated. It has been argued that in the conglomerate stage physical work is deleterious.

ous. No critical evidence bears on this important point. The silicotic man should of course be protected from any additional silica hazard in the environment.

Coal Worker's Pneumoconiosis. Exposure to the inhalation of coal dust without substantial quantities of silica appears to be rare, at least in the United States. Because of this and the fact that pure coal dust or carbon inhalation by animals produced no reaction similar to silicosis, it has been accepted that the nodulation and conglomerate masses seen in coal miners is in reality a modified form of silicosis. Recently the Pneumoconiosis Research Unit of Cardiff, South Wales, has reported studies strongly suggesting that in the miners of that area pulmonary injury occurs from the inhalation of coal per se rather than from the inhalation of silica. Histologic studies show that the earliest change is the deposition of pigment in a stellate-shaped discrete macule about which is a zone of emphysema. There is a delicate network of reticular fibers in these pigmented areas, but characteristically there is no hyaline deposition or extensive fibrosis such as typifies the silicotic nodule. These macules with their zone of focal emphysema are numerous and scattered throughout both lungs. This stage of the disease is categorized as simple pneumoconiosis of coal workers and is recognized in the roentgenogram by tiny nodulations which may coalesce into larger nodules or mottlings. The disease remains at this stage if no further exposure occurs and is characterized by a lack of symptoms. Physiologic studies show little or no abnormality of function in spite of the focal emphysema. When, as happens occasionally, a person with evidence of severe emphysema is seen at this stage, a nonindustrial or spontaneous origin of the emphysema must be strongly considered.

In certain cases of simple pneumoconiosis, irregular, large localized masses appear and progress in size. This stage is termed *progressive massive fibrosis* or *complicated pneumoconiosis* of coal workers. This stage is thought to be caused by coexistent infection, and tuberculosis is implicated in a high proportion of the cases. As the massive fibrosis develops, severe obstructive emphysema usually but not always becomes apparent.

It is of interest that this entity so closely parallels conventional silicosis, differing chiefly in that the focal emphysema is said to be more severe and the degree of fibrosis much less severe in the simple uncomplicated stage of coal worker's pneumoconiosis than is true of silicosis. Also, a high incidence of active tuberculosis and its rapid progression have not been reported in coal worker's pneumoconiosis. Typical changes have been reported in coal trimmers where silica exposure is considered nonexistent, hence the conclusion that they are the result

solely of coal dust. There is a divergence of incidence in different geographic locations of South Wales, and the incidence for South Wales is much higher than in other coal fields of Great Britain.

There are no critical studies to demonstrate whether or not this entity exists in other coal mining areas. Similar cases, both radiographically and histologically, are alleged to have been demonstrated in the United States. Many questions remain to be studied before the proper meaning of this interesting study from South Wales can be assessed in terms of the coal workers of other areas.

Asbestosis. The prolonged inhalation of sufficient quantities of asbestos fiber produces a diffuse fibrosis of the lung which may be extremely severe. The disease offers a contrast to silicosis in many features. Long fibers (20 to 50 μ) rather than short fibers evoke the tissue response; the irritant is mechanical rather than chemical; the lymphatic system is involved only slightly and late, the early lesion being a peribronchial fibrosis; the fibrosis is diffuse rather than nodular in character; severe pleural changes are common, interference with the passage of oxygen from the alveolus to the blood because of thickened alveolar walls is the characteristic physiologic alteration; diffuse obstructive emphysema is not manifested clinically or physiologically; clinical symptoms and physiologic abnormalities may precede unequivocal roentgenographic evidences of asbestosis; there is no alteration of susceptibility to tuberculosis. The diseases are similar in that the quantity of proper-sized particulates inhaled is the chief determinant of the development of diseases. Under usual working conditions, years of exposure are required to produce the disease. Severe disability (entirely different in fundamental character from that of silicosis) is likely to be present only in advanced cases; cor pulmonale, though a common cause of death in both, is more frequent in asbestosis. There is no effective form of treatment for the disease per se.

Pulmonary Granulomatosis of Beryllium Workers. An unusual chronic granuloma of the lung has been described in persons working where they may be exposed to the inhalation of beryllium and its compounds. Although an association with industries using beryllium compounds has been proved, the etiologic factors have not been determined. The disease is characterized in the severe form by extreme exertional dyspnea, paroxysmal cough, marked loss of weight, and cyanosis; the roentgenogram shows a diffuse ground-glass appearance of the lungs plus enlargement of the hilar lymph nodes. Interference with diffusion of oxygen across the alveolar membrane is the underlying physiologic defect and cor pulmonale the usual cause of death. Minute exposures to the chemical and a delay of months to years between exposure and onset of

the disease make this a most bizarre entity. The disease has more than just industrial implications, since bona fide cases have developed following the inhalation of exceedingly minute quantities of beryllium under nonindustrial circumstances. The number of cases is increasing. Differential diagnosis from other nodular granulomas is at times most difficult. No authentic spontaneous complete recovery has been reported. The mortality rate is high, but many persons remain in an arrested state of the disease for years. ACTH and cortisone have produced dramatic but not permanent remissions.

Byssinosis. This is a remarkable disorder of cotton mill workers exposed to high concentrations of cotton dust. It is characterized by chest tightness, wheezing, dyspnea, and cough. The symptoms recur each Monday (in those workers who have a Sunday holiday), are less intense on Tuesday, and then gradually disappear during the remainder of the week only to recur the next Monday. The cause of this peculiar and specific fluctuation is unknown.

After one or more decades, the symptoms may become persistent but still with exacerbation each Monday. Respiratory failure and/or cor pulmonale may ultimately occur.

During its early years, the disease is cured by cessation of exposure to cotton dust. However, this measure may be ineffective if instituted after irreversible pulmonary or cardiac changes have occurred.

Byssinosis is common in British workers and is occasionally seen in the United States.

264 BRONCHIECTASIS, LUNG ABSCESS, AND MISCELLANEOUS DISORDERS

John H. Knowles

BRONCHIECTASIS

The term bronchiectasis refers to a state of dilatation of the bronchial tree. The disease was first

described by Laennec in 1819. Extensive clinical study and description were made possible with the introduction of bronchography in 1922 by Sicard and Forestier. The incidence, prognosis, and severity of the disease have been radically altered with the advent of chemotherapy.

Bronchiectasis is a disease of *patchy* distribution in the lung. The affected segmental or subsegmental bronchus may undergo a tubular (cylindrical) or saccular dilatation. Generalized tubular dilatation of smaller (more peripheral) bronchi may be seen in chronic bronchitis and obstructive emphysema, but this is not of the same significance as the *localized*, more striking dilatation of larger (more proximal) bronchi seen in bronchiectasis. The differentiation of bronchitis and bronchiectasis is discussed below and on p. 1510.

Pathogenesis. Prolonged bronchial obstruction and infection must be present to cause irreversible dilatation of the bronchial tubes. If uncontrolled, the infection extends into the bronchial wall, with disruption of smooth muscle and elastic tissue, and invades the adjacent peribronchial tissue. Ciliated columnar epithelium is replaced by nonciliated cuboidal epithelium, and in some instances the entire bronchial wall may be replaced by fibrous tissue, with resultant formation of sacculi. With damage or loss of ciliated epithelium and loss of bronchial tone and peristaltic action there is further stasis of infected secretions. Traction by peribronchial and parenchymal scars distorts the diseased bronchus. In the region of third order bronchi, large (up to 1 mm in size) anastomotic communications between bronchial artery and pulmonary artery may be seen.

The posterior basal segments of the lower lobes are the most commonly involved. More than half of patients with left lower lobe disease also have involvement of the lingular segment of the left upper lobe. Upper lobe bronchiectasis is usually seen in the posterior or apical segment and is likely to be secondary to (old) tuberculous endobronchitis or to healed lung abscess.

Etiology. Prior to the introduction of antibiotics and extensive immunization programs, the commonest precursors of bronchiectasis were pertussis, measles, and influenza, and more than 50 per cent of patients dated the onset of their symptoms from the first decade. By giving rise to peripheral bronchial obstruction and stasis, these infections set the stage for superimposition of suppurative infection and bronchiectasis. At present *bronchopneumonia* is the most likely precursor of bronchiectasis. When drainage is hindered by inspissation of secretions or treatment is inadequate, there is delay in resolution and bronchial infection persists. Similarly, aspiration of a foreign body, particularly in children, and bronchogenic carcinoma and bronchial

adenoma by partially obstructing the bronchial lumen lead to chronic infection and the development of bronchiectasis distally.

Kartagener's syndrome consists of a triad of dextrocardia, sinusitis, and bronchiectasis. The incidence of bronchiectasis in patients with congenital dextrocardia is 15 to 20 per cent. The disease may never supervene in subjects with dextrocardia or it may develop late in life, depending probably on the element of infection. The reasons for the association are obscure.

Cystic fibrosis of the pancreas is a congenital disease characterized by exocrine pancreatic insufficiency and chronic obstructive pulmonary disease. Ninety per cent of deaths in cystic fibrosis are directly attributable to the pulmonary complication of obstructive emphysema, atelectasis, and bronchiectasis. Thick, tenacious secretions obstruct the bronchial lumen, resulting in atelectasis distally. If infection is superimposed (commonly with the staphylococcus or *Pseudomonas aeruginosa*), the ground is set for the development of bronchiectasis.

Bronchiectasis is a frequent complication of congenital *agammaglobulinemia* and results presumably from recurrent pulmonary infection. Only rare instances of bronchiectasis have been reported in adults in association with acquired agammaglobulinemia.

The right middle lobe bronchus is particularly vulnerable to compression by lymph nodes situated at its origin from the right bronchus. With enlargement of the peribronchial lymph nodes because of tuberculosis or nonspecific infection the right middle lobe bronchus is compressed and stasis and infection occur distally. This has been called the *middle lobe syndrome*.

Primary tuberculosis can lead to bronchiectasis via enlarged, obstructing lymph nodes at the root of a lobar bronchus. Secondary or reinfection tuberculosis may lead to a state of bronchiectasis by (1) distortion of subsegmental bronchi adjacent to a healing cavity or granulomatous lesion, or (2) destruction secondary to endobronchial tuberculosis.

Bronchiectasis, usually of the tubular type, may occasionally be seen in long-standing cases of bronchial asthma, chronic bronchitis, and obstructive emphysema. Presumably this has resulted from bronchial obstruction and infection due to viscid secretions and is patchy in distribution. Generalized dilatation of smaller bronchi may be seen in chronic bronchitis and emphysema (see below).

Bronchiectatic changes can frequently be demonstrated in the area of a healed lung abscess. Recirculation of lung abscess cavities and extension of suppurative disease to surrounding segmental bronchi result in their permanent dilatation.

Anomalous pulmonary arteries arising from the

aorta may be associated with sequestration of a lobe and resulting bronchiectasis commonly in the region of the posterior segment of the left lower lobe and close to the diaphragm.

Because of the frequent association of sinusitis with bronchiectasis, an etiologic role was assigned with the notion that chronic aspiration of infected sinus contents led to bronchiectasis. Similar reasoning has been applied to poor oral hygiene because of the rarity of healthy teeth and gingiva in patients with bronchiectasis. Perhaps this mechanism applies in a few individuals, but the association of upper and lower respiratory tract disease has not offered a convincing clue to the etiology of disease in either area.

Clinical Manifestations. Symptoms of bronchiectasis depend on superimposed infection and not the bronchial dilatation *per se*. Thus bronchiectasis may be continuously or intermittently symptomatic. Some individuals known to have bronchial dilatation in a lower lobe for many years have symptoms only after an upper respiratory tract infection. Upper lobe lesions may remain permanently asymptomatic because stasis and infection of secretions do not occur.

The cardinal manifestations are cough, mucopurulent sputum, hemoptysis, and recurrent pneumonitis. The cough is particularly severe and productive when the subject lies down, thereby emptying the contents of the dependent lower lobes into the larger bronchi. The morning production of sputum is large, and the patient may have syncopal episodes (cough syncope) or vomit (emetic cough) as he struggles to rid his bronchi of the overnight accumulation.

The sputum is mucopurulent and varies from 1 to 8 oz a day. It initially settles into three and finally into two layers as the frothy top layer subsides. The final two layers consist of an upper watery saline component and a lower heavier part consisting mainly of pus cells, and includes various organisms, Dietrich's plugs, and elastic tissue. The sputum (and breath) is occasionally foul smelling but usually has a sickish sweet odor and a pea-soup appearance.

Hemoptysis varies from blood-streaking of the sputum to massive and rarely exsanguinating amounts. In the former instance the blood has arisen from granulation tissue in the chronically infected bronchial wall and in the latter instance from erosion of a bronchial artery or a bronchial-pulmonary arteriolar anastomosis. Commonly in upper lobe bronchiectasis and occasionally with lower lobe disease, the initial symptom may be that of hemoptysis, so-called "dry bronchiectasis." Here cough and sputum production have been minimal (or minimized by the patient) and a subclinical, smoldering infection in a bronchiectatic segment

has finally eroded a vessel. Hemoptysis is said to be more common with sacular than tubular disease.

Recurrent pneumonitis commonly punctuates the course of bronchiectasis. A high index of suspicion should be aroused when recurrent pneumonia involves the same lobe repeatedly. In this case the reservoir of infection is the underlying infected bronchiectasis, and extension from here into the surrounding parenchyma has developed. Occasionally intrapulmonary aspiration of infected secretions from a diseased area into a healthy lobe has occurred.

More than 60 per cent of patients will have associated symptoms of sinusitis with postnasal drip and sinus headaches.

Dyspnea may be a prominent complaint in some patients, particularly older adults with extensive bilateral disease or an additional element of diffuse chronic bronchitis and obstructive emphysema.

On physical examination, the patient appears chronically ill. His wet cough frequently interrupts the examination. Sinus tenderness may be elicited. Clubbing of the fingers and toes is observed in 50 per cent of the patients. The chest may have the emphysematous configuration if accompanying diffuse chronic bronchitis is present. The most important finding is the auscultation of persistent, wet, coarse inspiratory rales at either or both posterior lung bases, more frequently the left, and over the right middle lobe or lingular segment of the left upper lobe. The breath sounds may be coarse and bronchial. The findings of diffuse chronic bronchitis may also exist (see Chap. 260). Examination of the heart may rarely reveal the findings of pulmonary hypertension. One should also be alert to the possibility of dextrocardia. There may be no abnormal physical findings in the chest in some patients.

Laboratory Findings. There is mild normocytic normochromic anemia if infection has been prolonged and severe. Leukocytosis may be seen if acute bacterial infection with pneumonitis is superimposed on the chronic infection. Urinalysis may reveal persistent albuminuria if the rare complication of secondary amyloidosis has occurred. The characteristics of the sputum have been alluded to above. Only occasionally do cultures reveal a predominant pathogen, particularly during an acute pneumonitis. Study of plasma protein electrophoretic pattern and of sweat electrolyte excretion may be useful in excluding agammaglobulinemia and cystic fibrosis, respectively (pp. 752 and 1666).

Pulmonary function is not measurably altered until the disease involves more than three segments or is bilateral. Decrease in vital capacity correlates with the extent of the disease. Some patients will show the pattern of obstructive emphysema, and their dyspnea correlates well with the reduction in

ventilatory reserve. Abnormalities of distribution as regards venous admixture effect (resulting in arterial oxygen unsaturation) may be minimized by the effect of the bronchial artery-pulmonary artery precapillary anastomoses in shunting returning venous blood away from diseased, poorly ventilated areas to normally ventilated areas where gas exchange is normally maintained. Pulmonary hypertension and cor pulmonale result when extensive bilateral disease destroys excessive parenchymal vascular bed.

Although the conventional x-ray of the chest may be normal in some cases, it is usually abnormal. Linear shadows extending from the hilum into the periphery of the lung field probably represent peribronchial thickening. Triangular shadows of lobar collapse may be seen at either lung base, particularly in children. So-called ring shadows—air-filled areas with thin or thick walls—may represent bronchiectatic sacs or local overdistention emphysema adjacent to atelectatic areas. With lobar collapse and in the rare instance of massive whole lung involvement, mediastinal contents will be shifted toward the diseased area and the homolateral hemidiaphragm will be elevated.

Bronchoscopy is ordinarily done prior to bronchography. It is an important diagnostic adjunct and helps in localization of the disease. It is also used to rule out bronchostenosis by external compression or by intrinsic tumor, foreign body, or endobronchial tuberculosis.

Bronchography is necessary to define the extent of the disease. The bronchial tree is outlined by the use of an aqueous iodine preparation called Dionosil. This is completely absorbed in several days in contrast to older oily preparations (Lipiodol) which might remain at the lung bases permanently. The bronchogram generally reveals a tubular or saccular dilatation of several or more of the proximal (second or third order) bronchi in the lung. The affected lobe is atelectatic, and the dilated bronchi are squeezed together.

A problem frequently arises in the differential diagnosis of bronchiectasis and chronic bronchitis, both of which may have the same symptoms and very similar bronchographic patterns and frequently coexist. Clinically sinus disease, copious amounts of sputum, hemoptysis, clubbing, wet rales which persist in a localized area of the lung over long periods of time, all seen in a youth or young adult patient, are highly suggestive of bronchiectasis. The middle-aged or elderly man with the chronic, poorly productive "cigarette" cough, signs of hyperinflated chest with quiet breath sounds, and generalized squeaks but no local wet bubbling rales more likely has chronic bronchitis and emphysema. There are several important radiographic points which may help in diagnosis: in

bronchitis the volume of the lung (or lobe) is increased, whereas in bronchiectasis it is decreased even though there may be emphysematous changes peripherally. In bronchitis the bronchi fill out more peripherally, whereas in bronchiectasis only the larger and more proximal bronchi fill. Bronchial diverticula, representing filling of the dilated ducts of mucous glands, are diffuse and sparse in chronic bronchitis. In bronchiectasis they are numerous and localized to the bronchus of the involved lobe. If both situations exist, then both diseases may be present.

The diagnosis of bronchiectasis should be suspected in any patient complaining of chronic and usually productive cough or hemoptysis or recurrent episodes of pneumonia. The suspicion is strengthened if clubbing is found along with persistent, wet inspiratory rales at the lung bases posteriorly or over the lingular segment or right middle lobe. If radiographic abnormalities are also seen on the plain film, the diagnosis is almost certain. It is strengthened by the bronchoscopic findings and confirmed by bronchography.

The course of the disease is extremely variable. Known bronchial dilatation may exist without symptoms for years only to become suddenly and persistently symptomatic. As a general rule, saccular bronchiectasis is a more serious disease than the tubular form, and bilateral involvement carries a worse prognosis than unilateral disease. It is of utmost importance to note that bronchiectasis is an acquired disease that is not, except in rare instances, progressive. It does not commonly spread and is ordinarily maximal when first seen. The typical patient prior to the antibiotic era was between fifteen and thirty years of age. His symptoms extended over 10 to 20 years, and their onset was usually dated from an episode of pneumonia or pertussis during the first decade of life. He was incapacitated by his foul sputum, general debility, and malnutrition. The individual whose illness began before ten years of age rarely lived beyond the age of forty, and the mortality of hospital cases followed for any length of time was 30 to 50 per cent. The usual causes of death were pneumonia, overwhelming sepsis, brain abscess, hemorrhage, and cor pulmonale. In addition to the complications, an occasional instance of secondary amyloidosis was recorded. More recent studies have shown that those complications now are exceedingly rare and that the prognosis has improved considerably, partly because of antibiotics and partly because more recent studies have considered ambulatory groups of clinic patients. Bilateral disease, persistent large amounts of fetid sputum, frequent bouts of fever, and clubbing of the fingers are poor prognostic signs. The presence of chronic bronchitis and obstructive emphysema also worsens

the prognosis. The mortality is now approximately 10 per cent over a 10-year period. The cause of death may be pulmonary insufficiency and cor pulmonale, but intercurrent and unrelated disease are also frequent causes. Surviving subjects rarely show progression of disease and fairly frequently show improvement.

Treatment. The treatment of bronchiectasis combines the judicious use of antibiotics, postural drainage (see Chap. 268, Therapy), and in certain patients resection of diseased areas. Antibiotic therapy is guided during periods of acute infection by the results of sputum (or blood) cultures. In patients who suffer repeated episodes of acute infection, small doses of antibiotics can be given prophylactically during the winter months. Periodic culture of the sputum should be obtained during such therapy to detect the emergence of other, sometimes resistant, organisms.

Because the disease is usually not a progressive or spreading process, every patient at least initially deserves a course of conservative medical therapy under close observation before a decision for or against surgery is made. The most dramatic surgical cures are effected by the excision of localized, unilateral disease which has remained symptomatic despite medical therapy. Massive and recurrent hemoptysis may also necessitate surgical removal. The poorest results are obtained with the excision of local disease in the face of bilateral, extensive disease and coexistent diffuse chronic bronchitis or bronchial asthma. Bronchitis or bronchial asthma is not cured by excision of bronchiectatic segments. Surgical therapy in general is not indicated where there is too little or too much disease. A period of conservative medical therapy is nearly always indicated, perhaps even for as long as a year, not only to judge its success or failure, but to avoid the mistake of resecting reversible or pseudobronchiectasis, recalling that the bronchial tree following the expansion of a collapsed lobe or the resolution of atypical pneumonia may take months and even a year to revert to normal with disappearance of bronchial dilatation.

BRONCHIAL OBSTRUCTION AND PULMONARY ATELECTASIS

Atelectasis refers to a state of incomplete expansion of the lung, due to failure to expand at birth (atelectasis of the newborn) or to collapse of pulmonary alveoli. This results from external compression (pleural effusion or pneumothorax) or bronchial obstruction. Collapse from external compression is ordinarily readily reversible with removal of fluid, air, or fibrous tissue (decortication) from the intrapleural space provided the underlying lung is normal. Atelectasis distal to bronchial ob-

struction is important for several reasons: (1) its discovery aids considerably in diagnosis as, for example, the lobar atelectasis seen in infancy associated with cystic fibrosis of the pancreas, and in childhood associated with compression of lobar bronchi by caseous nodes, or in adult life associated with bronchogenic carcinoma; (2) it is one of the prevalent causes of postoperative morbidity, and (3) it predisposes to lung abscess and bronchiectasis.

Bronchial obstruction with atelectasis may be caused by endobronchial disease such as tumor, stenosing inflammatory disease such as tuberculosis, foreign body, broncholiths, or inspissated mucous plugs; or it may be caused by extrabronchial compression by enlarged lymph nodes (middle-lobe syndrome), neoplasm, or aneurysm. Inspissation of mucus to form an obstructing plug is particularly common in patients with bronchial asthma, cystic fibrosis of the pancreas, or chronic bronchitis, in conditions associated with decreased movement of the chest wall, e.g., poliomyelitis, and in the early postoperative period.

Aspiration of foreign body, gastric contents, or of infected material from the upper respiratory tract occurs commonly and may result in pneumonia or abscess formation (see pp. 1554 and 1558) because of bronchial obstruction with distal infection. The defenses against aspiration of cough, laryngeal closure, and ciliary motion are impaired by sleep, alcohol, anesthesia, immersion and exposure, epilepsy, or coma from any cause. Aging per se results in a lessening of the airway's protective reflexes. Blood, mucus, dental deposits, or food may be aspirated, and the infected plug occludes the segmental bronchus. The right lung is more commonly involved because the right main bronchus is the straightest route for aspiration. The parts of the lung affected most often are the posterior segments of the upper lobes and superior segments of the lower lobes as these are the most dependent areas when in the supine or lateral decubitus positions, respectively. Foreign body, lung abscess, and aspiration pneumonia are discussed further below.

Obstruction of a main stem bronchus which develops gradually may give rise to mild, vague discomfort in the chest and little or no dyspnea. Acute obstruction of the same bronchus in the postoperative period (acute massive collapse of the lung) may be accompanied by anxiety, agitation, dyspnea, tachypnea, fever, and tachycardia.

Postoperative atelectasis occurs in about 5 per cent of patients, most commonly following upper abdominal procedures. It is more likely to be found in men, in smokers, in chronic bronchitics, in the aged, obese, and debilitated, and in patients incapable of early ambulation. Minimal degrees of atelectasis are heralded by mild fever (temperatures

to 101°F), tachycardia, and tachypnea within 48 hr after operation. Vague chest discomfort and mild respiratory distress and a cough, first nonproductive but later yielding tenacious mucus or mucopurulent sputum, are usual. If the collapse increases, expansion of the chest may be diminished on the affected side, and hyporesonance, inspiratory rales, and depressed breath sounds may be heard. The chest x-ray reveals linear shadows, usually in the lower lung fields, segmental or lobar atelectasis, or merely increased density of pulmonary parenchyma. If lobar or whole lung collapse has occurred acutely, it is heralded by severe agitation and anxiety, dyspnea and tachypnea. Hypoxia leads to cyanosis and acute systemic hypertension, and there may be substernal oppression if the mediastinum shifts toward the affected side. The percussion note may not be dull if the lung has not had time to lose enough air, but the hemithorax moves poorly and the trachea and heart are shifted toward the collapsed side. The x-ray shows the mediastinal shift, narrowing of the intercostal spaces, a high diaphragm, and a dense lobe or lung on the affected side. If the inspissated secretions are not removed, pneumonia may develop.

Treatment of atelectasis depends on the cause of the obstruction, and for this reason diagnostic bronchoscopy is always indicated in obscure cases. This procedure is also therapeutic in instances where removal of a foreign body or inspissated secretions is feasible. Therapeutic bronchoscopy may be necessary in postoperative cases if suctioning, percussion therapy, and coughing do not relieve the situation. The best treatment is preventive, however, and careful pre- and postoperative care will be amply rewarded.

FOREIGN BODIES IN THE AIR PASSAGES

The importance of aspiration of a foreign body in the genesis of pulmonary disease is frequently overlooked. The physician fails to elicit the history, the patient may have forgotten the event because of a symptomless interval following aspiration, and the various clinical syndromes produced are more readily explained by invoking the commoner disease processes which are mimicked, such as asthma, lung abscess, or bronchiectasis.

In order of frequency, the foreign bodies found are nuts, hardware, pins and needles, dental material, safety pins, and bone. A variety of predisposing factors are known, such as weakening of the defenses against aspiration, bad personal hygiene (loose teeth), or hasty eating. Inhalation of vegetable material such as a peanut causes a severe local and systemic reaction because its shape allows complete occlusion of a bronchus and it also incites

a chemical bronchitis. Irregular metallic objects usually produce only incomplete blockage.

A foreign body may shift its location in the lung or be passed to the opposite lung. Those which lodge in the trachea give rise to a palpable thud, an audible slap, and loud wheeze when expiration or cough forces the object against the inferior surface of the vocal cords. Death from asphyxia may occur. When a bronchus is occluded so that there is a "check-valve" effect with expiratory trapping of air, there will be distal emphysema, but complete obstruction leads to atelectasis and, finally, to drowned lung.

The initial episode may be violently symptomatic with severe cough, wheezing, dyspnea, and cyanosis. Bronchoscopy is an immediate necessity and is successful in removing the foreign body in most cases. If the level of obstruction is in a lobar or segmental bronchus, the initial fit of coughing may be followed by a symptomless interval of days or weeks after which chronic suppurative disease (lung abscess, bronchiectasis) develops. The patient may finally show the clinical picture of "asthma" and localized hyperinflation of the lung, lung abscess, or bronchiectasis. Bronchoscopy may not reveal the foreign body as overgrowth of granulation tissue may have obscured it. X-ray may show the radiopaque object which may also be confused with calcified hilar lymph nodes. Even though symptoms have been present for several years, removal of the foreign body can lead to complete restoration of apparently damaged lung. Therefore after removal, observation under medical therapy is advisable before deciding about the need for lobectomy.

BRONCHOLITHIASIS

Broncholithiasis refers to calcified concretions occurring in the tracheobronchial tree. They may arise in three ways: (1) by calcification of tracheobronchial cartilage and subsequent sequestration, (2) by secondary calcification of an exogenous foreign body, or (3) most commonly by migration and erosion of calcified material from hilar and paratracheal nodes into the tracheobronchial tree. The calcified node is the "tombstone" of the original disease, usually tuberculosis or histoplasmosis.

The condition occurs in both sexes equally and is most common between the ages of forty and sixty years. Cough and hemoptysis are the commonest manifestations and are due to bronchial ulceration or to intrabronchial location of the stone, with resultant obstruction and bronchiectasis. Recurrent chills and fever and purulent sputum may be noted, and 50 per cent of patients give a history of coughing up one or more stones. Some complain

of wheezing or "asthma" which is due to partial bronchial obstruction by the concretion. The right bronchial tree is involved twice as often as the left. Rarely, active tuberculosis is found distal to such an obstruction, and careful examination for tubercle bacilli is essential.

The x-ray reveals calcification of hilar or paratracheal nodes, atelectasis or pneumonitis with dense calcification at the apex of the affected lobe, or bronchiectasis on plain film or bronchography. Tomography may be necessary to delineate the relationship of calcification and bronchus.

The broncholith can be removed occasionally through the bronchoscope, but thoracotomy and broncholithotomy are usually necessary. Lobectomy is reserved for those patients who have persistent or recurrent symptoms or localized bronchiectasis.

LUNG ABSCESS

Etiology and Pathogenesis. The commonest etiologic factor in the development of primary lung abscess is aspiration of infected material from the upper respiratory tract, such as dental deposits (see above under Bronchial Obstruction). The virulence of the organisms and their ability to cause necrosis of tissue, the development of vascular occlusion due to septic endarteritis, and the pressure of increasing exudation combine to cause liquefaction of tissue within a few days. If the bronchus is eroded, partial drainage will lead to the formation of an air-fluid level. New abscesses or suppurative pneumonia can occur by direct extension or aspiration of pus into another segment. If healing is delayed, the cavity is lined by a downgrowth of cuboidal or squamous epithelium from connecting bronchi. Formerly, the differentiation of putrid (anaerobic) and nonputrid (aerobic) abscesses was stressed, but this is no longer regarded as important in therapy.

The following conditions predispose to abscess formation in the lung and should be considered in any patient with localized pulmonary suppuration:

Bronchial Obstruction. Most lung abscesses are initiated by bronchial occlusion, either by virtue of aspiration of infected material from the upper airway or the occurrence of an obstructing lesion, such as a tumor or postinflammatory bronchostenosis. Foreign body and bronchostenosis are relatively unusual. *Bronchogenic carcinoma* may be even commoner than aspiration as a condition leading to lung abscess in men beyond the age of forty-five. The abscess may be produced either by obstruction of the bronchus with distal stasis and infection of secretions or, more commonly, by necrosis and excavation within the tumor mass. Radiologically, the wall of the cavity is thick and irregular, the most important clue to the correct diagnosis.

Bacterial Pneumonia. Pneumonias due to the Friedlander bacillus, *actinomyces bovis*, pneumococcus type III, *Staphylococcus aureus*, and *Streptococcus hemolyticus* are occasionally complicated by true abscess formation because of the ability of these organisms to cause necrosis.

Vascular Embolism. Pulmonary infarction is a rare cause of abscess formation; less than 5 per cent of bland pulmonary infarcts are secondarily infected. Vascular embolization of infected material from osteomyelitis, suppurative pelvic disease (post-abortion), or phlebitis (for example, in a drug addict) can result in multiple small pulmonary abscesses.

Other Causes. Trauma to the chest may result in abscess formation by penetration of the chest wall by an infected foreign body, by infection superimposed on a traumatic pulmonary hematoma—a very rare event—or because of retained secretions due to reduced cough following rib fracture.

Stasis of secretions or aspiration of infected secretions into a congenital or acquired cyst may result in localized suppuration and accumulation of pus. The finding of a very thin wall with minimal surrounding inflammation may be a radiologic clue.

Amebic or pyogenic abscesses in the liver or beneath the right diaphragm may extend into the right lower lobe of the lung and result in abscess formation.

Clinical Description. The patient may present himself to the physician with acute or chronic symptoms. Following the initiating event, such as tooth extraction or an alcoholic debauch, there is a several day period of fever and malaise (representing segmental atelectasis and pneumonitis) followed by chest pain, usually pleuritic (extension of suppurative pneumonitis to pleural surface), and a dry cough. Anywhere from 4 to 10 days after the onset, the cough and fever become more severe (gangrene of lung). Scanty amounts of purulent blood-streaked sputum (erosion of bronchus) precede acute rupture of the abscess into the bronchial tree. When this occurs, the sputum becomes copious, and up to a liter of purulent and sometimes bloody sputum may be produced for the next several days. As free drainage continues, illness begins to abate, although the temperature may not become normal for several more days. When severe respiratory distress and prostration occur suddenly after the onset of pleural pain, rupture of the abscess into the pleural space with the formation of a pyopneumothorax has probably occurred. In acute lung abscess, if drainage of the area and antibiotic treatment are adequate, the patient will be free of cough and sputum production and constitutional debility after 10 days to 3 weeks of treatment, although complete clearing by x-ray and closure

of the cavity may take anywhere from 10 days to 4 months. If drainage is inadequate, the organism is resistant, or treatment is delayed, a necrotic slough forms in the cavity. Chronic cough and purulent sputum persist with intermittent fever and cachexia.

In the acute disease physical examination reveals a febrile, anxious patient with rapid pulse and respiratory rate. The oral hygiene is usually bad, and the gag reflex may be absent or diminished. Dullness and bronchial breath sounds and rarely a pleural friction rub may be heard over the diseased segment. Exquisite tenderness to palpation of the chest wall over the diseased area may be elicited because of pleural involvement. After bronchial communication has been established, amphoric breath sounds may be heard. Clubbing of fingers and toes is present within weeks of the onset in 10 to 20 per cent of cases and regresses with resolution of the disease. Rarely painful hypertrophic osteoarthropathy may occur, although this usually signifies underlying bronchogenic carcinoma.

Laboratory findings show a polymorphonuclear leukocytosis in the acute phase. With chronic lung abscess a normocytic normochromic anemia may develop.

The sputum is purulent and frequently bloody. Elastic fibers are present, indicating tissue destruction. Culture is essential and may reveal a single organism or varying combinations of beta- and alpha-hemolytic streptococci, staphylococci, occasionally pneumococci, *Hemophilus influenzae*, and *Escherichia coli*. Sensitivity to antibiotics must be determined. Anaerobic cultures will reveal the anaerobic streptococcus, fusiform bacilli, and spirochetal organisms. Sputum should also be examined for tubercle bacilli and malignant cells. Blood cultures obtained during the acute disease may yield the predominant pathogen.

Early in the disease the x-ray reveals segmental or lobar consolidation which assumes a spherical shape as the area distends with pus. Localization in the posterior segment of the right upper lobe or superior segment of the lower lobes should suggest the possibility of lung abscess. With rupture into the bronchial tree, an air fluid level appears. The wall of the abscess cavity should be inspected carefully. If very thin, with minimal surrounding pneumonia, the process may represent infection of a preexisting congenital cyst or bulla. If irregular and thick, cavity formation in a bronchogenic carcinoma may be at fault. Abscess due to Friedländer's bacilli may be multiloculated with many fluid levels, and staphylococcal abscess is frequently multiple, small, and thin-walled in a peripheral, subpleural location.

Bronchoscopic examination is necessary, particularly in the patient past forty or in any patient with

atypical features or delayed resolution, to rule out neoplasm as the underlying cause. In the child, foreign body must be considered.

Complications of lung abscess are very rare at present, with the exception of pyopneumothorax, and include exsanguinating hemorrhage, metastatic brain abscess, and secondary amyloidosis.

Differential diagnosis of the primary lung abscess includes tuberculosis, empyema with bronchopleural fistula, infected lung cyst, and peripheral carcinoma. Abscess formation must not be confused with the rarefied areas seen in a pneumonic consolidation undergoing normal resolution. Also transient ball-valve occlusion of the bronchus in an area of pneumonia may lead to acute tension cysts distinguished from lung abscess by their rapid onset and disappearance.

Treatment. The principles of treatment of lung abscess are similar to those involved in any suppuration—the establishment of adequate drainage and the eradication of infection (see also Chronic Empyema). Antibiotics and postural drainage are the mainstays of treatment. The longer the duration of symptoms prior to therapy, the less likely is medical cure, although every case deserves a trial of medical therapy initially. Treatment is begun with 2 million units of penicillin daily. The urgency of the situation and the results of culture dictate the need for an additional antibiotic to cover gram-negative organisms (see Chap. 268). Postural drainage is instituted, and its practice guided by the segmental localization of the abscess. A record of sputum volume is kept to follow the course of healing. Bronchoscopy may rarely be of therapeutic benefit. Tracheostomy and suctioning of secretions may be necessary in the weak or paralyzed patient. Clinical improvement occurs within days, and radiologic clearing usually becomes complete within 3 to 6 weeks. Segmental resection and lobectomy are reserved for those individuals who remain symptomatic and without continuous radiologic clearing during 3 to 6 weeks of continuous medical therapy.

MISCELLANEOUS TYPES OF PNEUMONIA

Aspiration Pneumonia

Aspiration pneumonia usually refers to the acute parenchymal inflammation associated with aspiration of infected material from the upper respiratory passages and to the condition associated with aspiration of water, food, or vomit. The same etiologic and pathogenic considerations described for lung abscess apply here, and indeed aspiration pneumonia will result in an abscess if necrosis is extensive. Aspiration of food and drink is particularly common in debilitated, elderly individuals. Pa-

tients with obstructing esophageal disease often develop chronic, bilateral lower lobe pneumonitis because of repeated aspiration.

Aspiration of gastric contents may occur in infancy and old age, in alcoholics and epileptics, and in subjects with head injuries, after the administration of drugs such as morphine, and during anesthesia. Maternal death during or following delivery may be due to aspiration of gastric contents. Rapid onset of acute toxemia occurs with high fever, tachycardia, cyanosis, tachypnea, and extreme dyspnea. Rhonchi and bubbling rales may be heard over the lower lobes. The x-ray shows bilateral lower lobe infiltrates with indistinct borders. There is necrotizing bronchopneumonia with hemorrhage, edema, and often multiple abscess. Treatment consists of immediate suctioning of the tracheobronchial tree and bronchoscopy as soon as possible. Penicillin and streptomycin should be given. Corticosteroids have been advocated to quell the chemical inflammation, although their effectiveness is not established.

Lipid Pneumonia

Lipid pneumonia is due to the repeated aspiration of animal oil (halibut and cod liver oil, milk, and egg yolk), vegetable oil (castor, olive, and wheat germ oil), or mineral oil. In the adult subject, the condition is almost invariably due to the chronic administration of mineral oil as a laxative or to drugs administered in an oily vehicle, such as nose drops. The condition is seen most frequently in elderly, bedridden, and chronically ill individuals, in short, those apt to have difficulty swallowing and to suffer from constipation necessitating the use of laxatives. Mineral oil apparently incites no cough reflex and moves unimpeded into the tracheobronchial tree. As it is chemically inert, it acts as a foreign body and incites a chronic inflammatory and granulomatous reaction. The disease is usually seen as a bilateral, lower lobe process but may rarely be confined to one lobe and simulate neoplasm (paraffinoma).

Clinically, nonspecific symptoms of mild cough and signs of scattered rales at the lung bases may be elicited. Most frequently the condition is asymptomatic and is discovered unexpectedly on routine x-ray examination.

The x-ray reveals increased lung markings, most notable at the lung bases early in the disease and scattered nodular and irregular infiltrates which become confluent in more advanced cases. Sometimes a local circumscribed density simulates bronchogenic carcinoma. The right lower lobe is the most frequent site of such a paraffinoma; hilar lymph nodes are not enlarged.

Examination of fresh sputum reveals characteristic macrophages filled with vacuoles which stain

positively for fat with Sudan III or IV. Their appearance may be intermittent, however, and several sputum examinations should be done.

The vital capacity is reduced in cases with extensive involvement, indicating a restrictive ventilatory defect due to replacement of air spaces with fat-laden inflammatory tissue.

The only treatment is cessation of the use of oil. When the disease is localized, pulmonary neoplasm must be excluded and exploratory thoracotomy may be necessary; when the disease is diffuse, tuberculosis and the diseases associated with interstitial fibrosis should be ruled out. One should not confuse cholesterol (or lipid) pneumonitis of endogenous origin (see p. 1528) with lipid pneumonia of exogenous origin.

Loeffler's Pneumonia and Pulmonary Eosinophilia

In 1932, Loeffler described a syndrome of transient pulmonary infiltration associated with peripheral blood eosinophilia and minimal or no symptoms. Mild cough, lassitude, and low-grade fever were associated with migrating, fleeting nodular pulmonary densities and mild leukocytosis with eosinophiles to 20 per cent of the total differential count. The disease was benign and self-limited, rarely lasted more than 3 weeks, and left no residual lesion. Although Loeffler initially thought this might be a manifestation of tuberculosis, subsequent studies by himself and others revealed infestation by ascari in some patients.

Since that time the association of pulmonary infiltration and peripheral eosinophilia has been described in a wide variety of conditions, and the term PIE syndrome (pulmonary infiltration with eosinophilia) has been used. Thus collagen disease, such as polyarteritis nodosa, malignant neoplastic disease, bronchial asthma, tropical eosinophilia, the Hamman-Rich syndrome, sarcoidosis, allergic reactions to drugs such as penicillin, the sulfonamides, PAS, organic arsenicals, barbiturates, and thiouracil, certain infectious diseases such as tuberculosis, coccidioidomycosis, brucellosis, or exposure to the privet plant, mite infection, and parasitic infestation have all been described as causes. The following parasites have been associated with the syndrome: *Ascaris lumbricoides*, *Necator americanus*, *Trichinella spiralis*, *Fasciola hepatica*, *Strongyloides stercoralis*, and *Ancylostoma brasiliense*. In the case of some of these parasites, such as ascari, larval migration through the lung doubtless gives rise to the syndrome and explains its transient, benign, and self-limited course.

The diagnosis of Loeffler's syndrome should be limited to cases conforming to his original description. In cases associated with persistence of symptoms and recurrence of x-ray abnormalities with

marked systemic reaction, a hypersensitivity angitis such as polyarteritis nodosa must be considered.

Tropical eosinophilia should be considered under similar circumstances, particularly in India and Ceylon or in natives from these countries. The condition consists of cough, paroxysmal dyspnea with bronchospastic, asthmatic attacks, splenomegaly in 50 per cent of cases, a positive Wassermann or Kahn reaction (which reverts after specific therapy), a high titer of cold agglutinins, and an x-ray showing bilateral mottled shadows. The sputum may contain many eosinophils. The white blood cell count ranges from 12,000 to 80,000, with 20 to 80 per cent eosinophils. A curious subacute degenerative syndrome affecting the cerebellum has been associated with the condition, being especially well documented in the French medical literature. Over 35 per cent of the cases respond to arsenical therapy, and this has been considered a diagnostic feature. It differs from Loeffler's syndrome in the presence of marked systemic reaction, persistence and chronicity of symptoms and x-ray findings, the striking response to arsenical therapy, and the occurrence of relapse in occasional cases.

Present theories of the causation of Loeffler's syndrome favor a local hypersensitivity state in the lung. Bronchial asthma, hypersensitivity angitis, or polyarteritis nodosa may represent other more diverse manifestations of similar immunologic processes.

CYSTIC DISEASE OF THE LUNG

Cysts of the lung may be either congenital or acquired, solitary or multiple. The congenital origin of cystic disease has been presumed because of its occurrence in infancy and childhood and its association with congenital heart disease, polycystic disease of the liver or kidneys, dextrocardia, and aberrant pulmonary vessels (pulmonary sequestration). Congenital cysts are of bronchial origin. Presumably, maldevelopment and failure of maturation of the terminal bronchial passages result in blind rests lined with bronchial epithelium, which usually communicate with the bronchial tree.

Acquired cysts develop from the rupture and coalescence of alveoli and are thus "alveolar in origin." When the air collection lies between visceral pleura and lung substance it is termed a *bleb*. They occur commonly at the apices and ordinarily have little functional significance. The term *bull* refers to an air space more than 1 cm in diameter, situated in the substance of the lung, and frequently seen in association with obstructive pulmonary emphysema. Acquired cysts may be seen as a sequel to lung abscess (due to epithelialization of the cavity), pneumonia, tuberculosis,

fungous disease such as coccidioidomycosis, or echinococcus disease.

Air cysts are ordinarily asymptomatic. The patient may suffer one or more of the complications which are (1) infection, (2) hemorrhage, (3) rupture of blebs or subpleural cysts with pneumothorax formation or rupture of bullae with interstitial and mediastinal emphysema, and (4) respiratory insufficiency. Repeated infection is what usually necessitates surgical removal of the diseased area. Communication with the bronchial tree determines the clinical behavior and functional deficit. The cyst may be air filled and remain stable in size over long periods if it communicates freely. If the opening is small and is intermittently occluded, the cyst may enlarge progressively as air trapping occurs on expiration and may intermittently become infected and fluid filled. In infancy large unilateral cysts called pneumatoceles may develop rapidly in association with pneumonia and occupy the entire hemithorax. In adults, a progressively enlarging bullous lesion may replace an entire lung and is referred to as the "vanishing lung syndrome." Multiple cysts are usually bilateral and may simulate bronchiectasis in their clinical course.

The development of respiratory insufficiency depends on the communication of the cyst, its size and the degree of parenchymal replacement or compression, and the presence of obstructive emphysema. If the cyst is large and communicates freely with the bronchial tree, the effect is an increase in dead space ventilation, as the wall of the cyst is poorly vascular and gas exchange does not occur. If the cyst communicates poorly or intermittently with the respiratory tree, air trapping and, as the cyst grows larger, compression of the surrounding parenchyma occur. Obstruction to air flow and reduction in lung volume may be seen, and dyspnea is thus due to both obstructive and restrictive ventilatory defects. Arterial oxygen unsaturation occurs if ventilation to surrounding parenchyma is reduced more than perfusion, leading to a venous admixture effect.

The presence of associated obstructive emphysema must be detected prior to surgical removal of pulmonary cysts. Fluoroscopic demonstration of contralateral air trapping and restriction of diaphragmatic motion, great reduction in maximal breathing capacity, and large increase in residual lung volume may be helpful differential points. The finding of respiratory acidosis with an elevated CO_2 tension in the arterial blood nearly always indicates the presence of underlying, severe obstructive emphysema and virtually precludes surgical therapy. This is not true of oxyhemoglobin unsaturation as an isolated abnormality of the blood gases, as this may be relieved by surgical excision of a large cyst.

Physical examination may be unremarkable. Tracheal deviation may be seen with large unilateral, poorly communicating cysts as well as mediastinal shifting toward the lesion on inspiration and away on expiration. Rales may be heard if there is infection or bronchiectasis adjacent to the cyst. Large unilateral air cysts simulate pneumothorax with hyperresonance, decreased or absent breath sounds, and tracheal deviation.

Radiologically the cysts are usually thin-walled and multiple but may be solitary and easily confused with lung abscess, bronchiectasis, chronic nonspecific pneumonitis, staphylococcal pneumonia, and tuberculosis. Pneumothorax and encapsulated empyema with bronchopleural fistula must also be differentiated. Generally the same principles of medical treatment apply here as in lung abscess (see p. 1555).

CHRONIC EMPYEMA

Chronic empyema is a persistent collection of pus or fibropurulent material in the pleural space. In over 75 per cent of cases, the cause is inadequate treatment of acute empyema. Underlying lung disease such as bronchiectasis, lung abscess, tuberculosis, mycotic infection such as actinomycosis, and bronchogenic carcinoma may be the initiating process which has rendered the condition chronic and difficult to treat. Other causes for chronicity include the formation of a bronchopleural fistula leading to repeated infection of the area. Occasionally a foreign body is present in the empyema cavity, such as a rubber drain or a sponge left behind from previous drainage.

The pathologic change is essentially one of intense fibrous thickening of visceral and parietal pleura due to chronic fibrin deposition and organization. The cavity may be multiloculated because of formation of fibrous septums. If the underlying lung is diseased, as in tuberculosis or bronchiectasis, fusion of the visceral pleura with parenchyma may be such that separation is impossible.

The history may extend anywhere from 6 weeks to 20 years or more. It is of utmost importance to obtain details of the diagnosis and treatment of the acute illness, usually pneumonia. A history of tuberculosis, previous thoracic surgery, bronchiectasis, or in the case of older subjects, one suggestive of bronchogenic carcinoma may provide the etiologic clue and thus direct management. The symptoms of chronic empyema may be surprisingly few as in tuberculosis where the pleural infection may remain latent for years. A poorly productive cough with recurrent febrile episodes, chronic fatigue and malnutrition, intermittent drainage of pus from the scarred site of previous drainage, and moderate dyspnea may occur. Intermittent expec-

toration of purulent sputum may indicate the presence of bronchopleural fistula.

The physical signs depend on the duration of the process. The scar of a previous drainage site may contain a small cutaneous fistula and intermittently discharge pus and air. The hemithorax is contracted and poorly expansile. Its muscles are wasted. Scoliosis may be present, with the convexity toward the normal hemithorax. The percussion note is dull and the breath sounds are decreased or bronchial if underlying lung is sufficiently compressed. Amphoric breath sounds and air bubbling through fluid may be heard in the presence of a bronchopleural fistula. Clubbing may occur. Secondary amyloidosis and cerebral abscess are unusual complications. Penetration of the chronic infection through the intercostal soft tissue with spontaneous drainage through the skin of the chest wall may occur rarely (empyema necessitatis), but particularly with mycotic infection.

The normochromic, normocytic anemia of chronic infection may be seen along with the hypoproteinemia of malnutrition. Persistent albuminuria may be found if secondary amyloidosis has involved the kidneys.

Röntgenograms of the chest reveal an asymmetrically small hemithorax with crowded ribs which may appear to overlap ("tiling"). An area of rib resection and bizarre, irregular periosteal proliferation may be seen in previously treated cases. The area of empyema may be represented by radiopacity of the entire hemithorax, or there may only be a basilar density obscuring the hemidiaphragm with a rim of thickened pleura extending to the apex of the lung. An air-fluid level may be seen if a bronchopleural fistula is present. A grid film may reveal the condition of the underlying lung as well as demonstrating the thickness of the pleural walls of the empyema cavity. Calcification of the pleura may be seen in cases due to tuberculosis or infected hemithorax.

The thickened pleura encases and compresses the lung, preventing its expansion and contraction. The vital capacity is reduced in proportion to the severity of the restrictive ventilatory defect and accurately mirrors its extent. Dyspnea of more than a mild degree is unusual when the contralateral lung is normal. When extensive underlying pulmonary disease is present (e.g., tuberculosis, bronchiectasis), the entire lung may be nearly functionless and represents a "physiologic autonecrotomy." The extent of the underlying lung disease and the duration of the empyema determine the degree of functional improvement following therapy (e.g., pleural decortication). The disease may have been present for years, and still reexpansion and excellent return of function may occur following surgery.

The management of chronic empyema depends on the etiology and the presence or absence of underlying pulmonary disease. Thoracentesis with withdrawal of fluid for examination and culture (routine as well as for tubercle bacilli and fungi) is necessary. The fluid is purulent or fibropurulent and has a high specific gravity (>1.028) and protein content (>4.5 Gm per 100 ml). Varying numbers of polymorphonuclear leukocytes and lymphocytes may be present along with much amorphous debris. Lymphocytic effusions with absence or paucity of mesothelial cells should arouse suspicion of tuberculosis. A pleural biopsy should be done at the time of thoracentesis with the Vim-Silverman needle. If this is unrevealing (as regards fungous disease or tuberculosis), a generous biopsy should be obtained at the time of surgical therapy. The extent of the empyema sac should be determined by introducing air or radiopaque material after diagnostic thoracentesis. If there is any suggestion of underlying lung disease, bronchoscopy and bronchography should be considered, as the results will have a direct bearing on therapy and prognosis. Culture of secretions obtained at bronchoscopy should be done both routinely and for tubercle bacilli. Tuberculin and fungus skin testing as well as gastric aspiration for culture of the tubercle bacillus should be done where indicated.

The principles of successful treatment are eradication of infection and obliteration of the empyema space, with freeing of the underlying lung. Thoracotomy with local rib resection and drainage of the empyema sac under cover of appropriate antibiotic therapy is usually the first step. Excision of the empyema sac and pleural decortication may be necessary ultimately. Drainage and local thoracoplasty are occasionally employed to obliterate the cavity. In some cases with extensive parenchymal disease, pneumonectomy is performed.

It is important to distinguish the postpneumonic empyema, now sterile and resolving slowly in a clinically well individual, from the chronically infected collection adversely affecting the patient. Very frequently persistence with conservative therapy will result in complete resolution in the former, while it may do great harm in the latter situation.

265 NEOPLASMS OF THE LUNG

Champ Lyons

CARCINOMA OF THE BRONCHUS

The great majority of the neoplasms of the lung arise within the wall or epithelial lining of the bronchus, either centrally or peripherally. About half of all bronchogenic carcinomas are squamous cell types. About one-third are highly anaplastic and are designated as undifferentiated carcinoma. These two types occur predominantly in males. There is considerable sentiment to indict the smoking of cigarettes in the genesis of lung cancer, but there are still two sides to the question. More clearly carcinogenic are the industrial exposures in the mining of radioactive ores, the refining of nickel, the manufacture of chromates and coal gas, and the processing of arsenic and asbestos. The siliceous dusts, as encountered in mining, do not seem to increase the vulnerability of the lung to cancer.

About one-fifth of bronchogenic cancers are adenocarcinoma. These occur with almost equal frequency in females, and it has been suggested that they arise from embryonic bronchial buds. They are usually highly malignant.

Early lymphatic and vascular invasion are so constantly a feature of bronchogenic carcinoma that initial symptoms in many cases are attributable to metastases. These involve the mediastinal and supraclavicular lymph nodes, brain, bone, adrenal cortex, liver, and subcutaneous tissues. Tumors arising in the apex of the lung may invade directly the brachial plexus and subclavian vessels producing neuritic pain, Horner's syndrome, and vasomotor crises in the hand and arm, the *Pancoast syndrome*

of superior sulcus tumor. Secondary involvement of the superior mediastinum may compress the superior vena cava, with resulting edema and venous suffusion of the face, neck, and arms, the *superior vena caval syndrome*. Less frequently, direct invasion of the esophagus behind the heart may be responsible for obscure dysphagia.

Another pattern of symptoms is to be attributed to the encroachment of the tumor upon the lumen of the bronchus or bronchiole. With partial occlusion of the lumen there is persistent cough, asthmatic breathing, and x-ray evidence of localized emphysema. As the obstruction becomes complete, there is atelectasis, recurrent pneumonitis, distal bronchiectasis, and occasionally, lung abscess. Hemoptysis is fairly common in both the early and the late stages.

Extrapulmonary manifestations unrelated to metastatic spread may dominate the initial symptomatology. Clubbing of the fingers, with or without painfully swollen joints (pulmonary osteoarthropathy), is the most frequent peripheral sign of bronchogenic carcinoma. Migratory phlebitis and peripheral neuropathy are similarly associated as are, less commonly, hypercalcemia and Cushing's syndrome.

Apart from the demonstration of localized emphysema and segmental atelectasis, the most suggestive x-ray finding is that of a hilar density extending peripherally (see Fig. 263-1). Bronchoscopy permits visualization and biopsy of the primary tumor in 40 to 60 per cent of the cases. Cytologic study of the sputum, in expert hands, may permit diagnosis in 85 per cent, and is especially useful for peripheral tumors. Early recourse to exploratory thoracotomy with biopsy of the primary tumor or regional nodes is the procedure of choice in any controversial diagnosis. Contrast bronchography is rarely indicated.

The treatment of choice for bronchogenic carcinoma is radical pneumonectomy. It is of great clinical concern that about one-half of the symptomatic patients, presenting at an average lapse of 5 months from onset, are rejected for operation on the basis of local extension or distant metastases. About one-third of the symptomatic cases prove to be resectable, and the 5-year survival rate is about 6 per cent. In older patients with reduced respiratory reserve, less radical resections, such as lobectomy or partial pneumonectomy with plastic reconstruction of the bronchus, have proved practical without apparent reduction in the salvage rate. X-ray treatment and nitrogen mustard therapy occasionally retard the rate of growth and spread.

Identification of the presence of a tumor before the onset of symptoms remains the chief hope for greater salvage. Mass radiography for tuberculosis has provided numerous instances of the silent and

"solitary nodule." Many of these have proved to be totally resectable cancers. The problem of early recognition of cancer of the lung is now so pressing that all males over forty should have x-ray examination of the chest at intervals of 6 months. It is to be expected that refinement of cytologic techniques may contribute to early diagnosis.

Carcinoma of the bronchus should also be suspected whenever any individual in the susceptible age group shows delayed resolution of any intrapulmonary inflammation. The unresolved pneumonia or a lung abscess or pneumonia recurrent in the same lobe in males over forty should invite immediate study for tumor.

The Problem of the Solitary Pulmonary Nodule. Occasionally, a roentgenogram of the chest may reveal a nodule, less than 6 cm in diameter, which is fairly sharply delineated from adjacent pulmonary tissue. Such lesions have been designated solitary pulmonary nodules, in preference to the term *coin lesions*. About one-third of these are peripheral bronchogenic carcinomas, demonstrable as such only after excision. (Simple lobectomy can be expected to result in a cure in 75 per cent of these patients.) In the absence of other diagnostic aids, thoracotomy is indicated by the x-ray findings in most cases. Ten per cent of such lesions are metastatic neoplasms, and about half are granulomas, with histoplasma, tuberculosis, and coccidioidomycosis responsible in that order. Hamartomas, lipid granulomas, lipid granulomas from oily nose drops, and pulmonary sequestrations also produce this picture. A nonoperative program of continued observation may be elected when a review of earlier films demonstrates no change over a period of 5 years, but it should be realized that such nodules have been followed for 8 years, only to declare themselves as cancers. Considerable interest in radiologically demonstrable calcium deposits has demonstrated that "flecks" of calcium may occur in bronchogenic cancers. A central core or concentric lamellations of calcium are indicative of granuloma. (See also Table p. 1509, Some of the Causes of Puzzling Radiologic Pulmonary Shadows.)

BRONCHIOLAR CARCINOMA

This disease has been known as *pulmonary adenomatosis*, but the ultimately fatal outcome and the increasing recognition of regional and distant metastases render suspect the identity of completely benign pulmonary adenomatosis. It is not certain whether the tumor cells are derived from the basal cells of the terminal bronchioles or from the lining membrane of the alveoli. Usage dictates preference for *alveolar cell carcinoma*, or *bronchiolar carcinoma*. There occurs in sheep a contagious

FIG. 265-1. Carcinoma of the bronchus.

disease, of presumptive viral etiology, known as *jaagziekte* in South Africa, and as *Montana chronic progressive pneumonia* in the United States. This disease is not transmissible to man, but is characterized by hyperplasia of cuboidal epithelial cells within the alveoli in striking similarity to the neoplastic disease of man.

The tumor appears to arise from multicentric foci, and ultimately involves both lungs. Both sexes are susceptible, and the usual age of onset is in the fourth and fifth decades. Symptoms begin insidiously, often following an acute respiratory infection. Cytologic examination of the sputum, even in early cases, frequently reveals tumor cells. Dyspnea, because of faulty gas exchange, is out of proportion to x-ray findings. Cough productive of the typically viscid pinkish sputum is a manifestation of the tumor. Terminally, there is frank hemoptysis with clubbing, intense cyanosis, recurrent pneumonitis, and evidence of metastasis. Nodular and confluent patterns of the disease are recognized.

The treatment of choice is surgical excision of the initially involved lobe or lobes, when practical. There is some hope of palliation by x-ray therapy, but nitrogen mustard appears useless.

ADENOMA OF THE BRONCHUS

The bronchial adenoma is a locally invasive and occasionally metastasizing tumor derived from the mucous glands of the bronchus and requiring separate classification from the more rapidly growing bronchogenic carcinomas. It constitutes about 3 per cent of all lung tumors and differs from

FIG. 265-2. Hematogenous metastasis from sarcoma of the ileum marked by intense dyspnea and cyanosis. (Courtesy, Dr. C. L. Martin.)

bronchogenic carcinoma in that it is usually apparent before the fifth decade, lacks sexual predilection, and develops metastases persisting for long periods without apparent change.

Histologically the adenomas show a peculiar epithelial proliferation and an equally peculiar stroma. Inclusions of bone are thought to represent metaplasia from chronic infection. The mixed tumor (cylindroma) type (10 per cent) is somewhat more invasive than the carcinoid adenoma (90 per cent). There is still controversy about these tumors as regards etiology, the occurrence of mixed types, the absence of argentaffin granules in the types designated as carcinoid, and their relationship to other polypoid tumors of the bronchial wall.

The adenoma syndrome is the clinical consequence of the slow growth of a vascular tumor producing major bronchial occlusion in a young person, i.e., hemoptysis, asthmatic wheezes, obstructive emphysema, recurrent pneumonitis, and the complications therefrom: bleeding, atelectasis, bronchiectasis, pleuritis, lung abscess, and empyema. The lower lobes are more often affected, and there is a slightly greater incidence on the right side. Contrast radiography (bronchography or tomography) often demonstrates the tumor, but routine x-rays are noncontributory in about one-fifth of the cases. About 90 per cent of the tumors may be recognized bronchoscopically by their polypoid appearance, mobility, vascularity, and absence of ulcerations. The vascularity dictates caution in the indicated biopsy. The lack of ulceration explains

the absence of tumor cells in sputum and bronchial washings.

Older methods of piecemeal excision by repeated bronchoscopic nibblings have largely been replaced by direct surgical removal of the primary tumor, the involved hilar lymph nodes, and the secondarily diseased lung. Exceptions to pneumonectomy consist of lobectomy for the more peripheral tumor without involvement of hilar nodes, and bronchotomy for the small tumor with a tiny stalk. Long term survival is the rule, especially for the carcinoid adenomas. Mediastinal recurrence and hepatic metastases are an especial hazard of the mixed tumor adenomas (cylindromas). There is some evidence to suggest that true bronchogenic carcinoma may occasionally develop within an adenoma.

METASTATIC TUMORS OF THE LUNG

Metastasis to the lung results from infarction with tumor emboli carried by the peripheral veins. The x-ray appearance is frequently characteristic and may appear as a solitary "cannonball" nodule, multiple nodules (see Fig. 265-2), or miliary dissemination known as *lymphangitic carcinomatosis* (see Fig. 265-3). It is hazardous to make an x-ray diagnosis of lymphangitic carcinomatosis of the lung in the absence of clinical evidence of alveolar capillary block, namely, severe dyspnea and obvious cyanosis. Sarcomas, hypernephromas, melanomas,

FIG. 265-3. So-called "lymphangitic carcinomatosis," metastatic from a carcinoma of the cervix. (Courtesy, Dr. C. L. Martin.)

and tumors of the testicle, breast, thyroid, and pancreas seem to find the lung an especially favorable site for the growth of metastases.

Dyspnea and pleuritic pain are the cardinal symptoms of lung metastases. Erosion into the bronchial tree may be associated with cough, hemoptysis, and occasionally, with tumor cells in the sputum. Treatment is largely palliative, with opiates and repeated thoracenteses to relieve the pain and dyspnea. Irradiation may prove helpful for sensitive tumors, but more reliance is placed upon hormonal or isotope approaches for specific tumors.

In the course of exploratory thoracotomy for asymptomatic solitary nodules, it occasionally happens that a metastasis from a previously unidentified primary tumor is found. The ground rules for deliberate surgical excision of solitary lung metastases include prior control of the primary focus, lapse of a reasonable length of time between initial treatment and appearance of the lung metastasis, and absence of other areas of tumor recurrence.

PRIMARY TUMORS OF THE PLEURA

Localized pleural tumors are usually proved to be mesenchymomas of subpleural mesodermal elements or granulomatous inclusion cysts complicating interlobular inflammation. Primary pleural neoplasms are restricted to the mesothelioma. This may occur as a localized tumor, frequently arising from the visceral pleura or embedded in the lung and distinctively associated with clubbing and arthralgia which disappear after removal of the tumor. The diffuse mesotheliomas require difficult differentiation from metastatic anaplastic carcinoma with pleural effusion and are characterized by a comparably intractable course. Treatment is limited to repeated thoracenteses, radiation therapy, and institution of radioactive gold as palliative procedures.

266 DISEASES OF THE PLEURA, MEDIASTINUM, AND DIAPHRAGM

Ben V. Branscomb and
T. R. Harrison

THE PLEURA

Hydrothorax

The typical physical signs of the accumulation of noninflammatory fluid in the pleural cavity include prominence of the interspaces on the affected side, which displays a dull to flat percussion note with diminution of breath sounds and of spoken and whispered voice. The heart and trachea tend to be displaced toward the normal side of the chest, and the circumference of the involved side may be demonstrably greater by measurement. Certain aspects of this disorder have been considered in the chapter dealing with congestive heart failure, which is much the commonest cause. Less frequently, hydrothorax may occur in persons with hypoproteinemia due to nephrosis or cirrhosis, or it may be caused by neoplastic or traumatic disorders involving the thoracic duct. In the latter instance the fluid is chylous, with a milky appearance due to the presence of fat droplets. The mechanism of the accumulations of pleural fluid associated with benign tumors of the ovary (Meigs' syndrome) remains to be clarified.

An unusual variety of hydrothorax is that due to an interlobar effusion. The resulting rounded mass is likely to be confused with a neoplastic shadow but tends to disappear as cardiac failure improves (phantom tumor). The distinction of the noninflammatory hydrothorax from effusions due to pleuritis is discussed below. The treatment is that of the underlying cause of the condition plus the withdrawal of fluid by puncture when this is needed for the relief of dyspnea (p. 1584).

Pleuritis

The widespread radiation of pain arising from pleural irritation has been previously considered

(p. 15). The cardinal feature of the pain is its sharp stabbing quality, with aggravation by deep inspiration and, particularly, by the more sudden respiratory acts such as coughing and sneezing.

Inflammation of the pleura is commonly due to infections, the most frequent being tuberculous, the bacterial pneumonias, and the various viral diseases which affect the respiratory tract. Much less frequently pleuritis is the result of the spread from below of a subdiaphragmatic or hepatic abscess. Ischemic pleuritis consequent to pulmonary infarction is perhaps the second commonest cause. However, pleural involvement due to collagen disease, especially by rheumatic fever or disseminated lupus, or to neoplasm is not unusual. Trauma is an occasional cause.

Fibrinous Pleurisy. Acute fibrinous or dry pleurisy occurs in most persons at some time in their lives and is rarely serious. The clinical manifestations are those of the associated causative disease, which is usually a respiratory infection, pleural pain, and the characteristic friction rub, which is absent in many instances. This pleural friction sound must be distinguished from respiratory wheezes.

Fibrinous pleurisy must be distinguished from pain arising in the structures of the chest wall and, particularly, from fractured rib. The latter condition may also produce pain on breathing but is especially apt to be accompanied by discomfort on specific motions of the body, such as turning or twisting, and may be associated with exquisite tenderness over a sharply localized area.

The treatment of dry pleurisy is largely that of the causative disorder. If pain persists despite voluntary restriction of respiratory excursion, mechanical measures which limit chest motion may be used. These include lying on the affected side, the use of chest binders to limit intercostal and promote diaphragmatic excursion, and strapping of the affected area with adhesive plaster. If a productive cough is present, binders should not be used. Here, application of heat, spraying the chest with ethyl chloride, or occasionally intercostal nerve block will be helpful.

Pleuritis with Effusion (Serofibrinous Pleurisy). In general, the seriousness of pleural effusion depends on that of the underlying cause. However, the effusion itself may produce dyspnea due either to the marked encroachment on lung volume or to the shallow breathing made necessary by the pain. Pronounced pleural reaction, such as sometimes occurs with effusions, may cause permanent impairment of pulmonary function with constrictive pleuritis, which increases the work of breathing and interferes with filling of the lung in the same way that constrictive pericarditis hampers filling of the heart.

Three diagnostic problems are involved in patients with pleural effusion. The first is the recognition of the presence of the fluid in the chest. This depends on the radiologic and physical findings which have been mentioned in relation to hydrothorax. The second problem is the distinction of inflammatory from noninflammatory effusions. This depends in large measure on the associated findings such as pleural pain and friction, which are absent in patients with simple hydrothorax. The character of the pleural fluid (see below) is also of great importance in this distinction.

The third diagnostic problem is that of the detection of the underlying cause, once an effusion has been recognized to be of the inflammatory type. Here, the total clinical picture will often be decisive, as when rheumatic fever or typical lupus erythematosus is the cause. Similarly, there will be no doubt when the patient presents the classic evidences of lobar pneumonia or those of phlebotrombosis plus pulmonary infarction. However, in many instances the cause of the effusion will not be immediately apparent, and the diagnosis will depend in large measure on careful examination of the fluid itself.

When pleural fluid is removed, a portion should be drawn into a vessel containing an anticoagulant. Otherwise, clotting may prevent its careful study, which is often essential for diagnosis. The examination should include gross inspection, measurement of specific gravity, cell content, and the utilization of appropriate staining and culture methods for tubercle bacilli, fungi, aerobic and anaerobic bacteria. The content of protein should be measured, and cytologic examination for malignant cells should be made. If the fluid is withdrawn and discarded, it may subsequently be difficult to obtain a sufficient quantity for study and the opportunity for diagnosis will have been lost.

Gross inspection may reveal the obviously purulent fluid of empyema (p. 889) or the milky appearance of chylothorax—usually the result of traumatic or neoplastic damage to the thoracic duct. Blood is usually present in fluid due to carcinoma or infarction but may also be seen in the effusions of tuberculosis, congestive failure, and other diseases.

The specific gravity is helpful in separating the transudates from the exudates. About three-fourths of the patients with congestive failure have fluids with specific gravity of less than 1.016, and a similar percentage of patients with tumor or tuberculosis have values greater than 1.016. The separation of the transudates from the exudates is somewhat more precise when a protein concentration of 3 Gm per 100 ml of fluid is used as the dividing value.

The organisms can be recovered by smear or

culture in about two-thirds of the tuberculous fluids. The leukocyte and differential counts are of little value in establishing the etiology of nonpurulent effusion.

Needle biopsy is simple and often provides early histologic diagnosis. However, it must be carried out when sufficient effusion of air is present to separate the pleural surfaces. For this reason, the procedure should be considered early—prior to aspiration of all the fluid. In the hands of a pathologist skilled in the distinction between malignant and inflammatory endothelial cells, a correct cytologic diagnosis of neoplastic disease may be made in more than half the patients with malignant effusions. This finding seems to be independent of the presence of blood.

Tumors of the pleura cause massive and often rapidly recurring effusion. The x-ray frequently shows masses or sheets of tissue implanted on the pleura, especially if the fluid is removed and air injected into the space. The most common neoplasms are carcinoma of the lung and breast, lymphomas, and less often, primary pleural mesothelioma. Benign pleural fibroma is a rare but curable cause of effusion.

In a considerable proportion of patients with pleural effusion, doubt as to the cause will remain even after the most thorough consideration of the total clinical picture and the most meticulous examination of the fluid. The tendency to designate such patients as having "idiopathic pleural effusions" should be condemned. It has been properly said that the term idiopathic applied to such a patient is idiotic from the standpoint of the physician and pathetic from that of the patient. Such confusion of a name with an explanation may lead to a false sense of security and a failure to pursue the careful future following which is necessary in all patients with effusions of undiagnosed cause. It is likely but as yet unproved that viral infections are responsible in many instances, and in these, no further complications are to be expected. However, pleural effusion may be the earliest and the sole manifestation of tuberculosis, and many such patients will subsequently develop lesions in the lungs or elsewhere. Therefore, repeated subsequent careful examinations are essential. One or more attacks of pleuritis with effusion may be the sole manifestation of pulmonary infarction.

The first principle in the management of the patient with pleuritis and effusion is the treatment of the underlying causative disorder. The second is the appropriate utilization of thoracentesis. This procedure is indicated for diagnosis in almost all instances, and is frequently needed for the relief of dyspnea. Thoracentesis is likewise indicated to promote reexpansion of the lung and prevent its future mechanical deformity when spontaneous

resolution of the fluid fails to occur within a few weeks. The purulent fluids constitute special problems, and these have been considered in a previous chapter (p. 893).

Chronic Adhesive Pleuritis. All degrees of this disorder exist. A few small adhesions between the parietal and visceral layers is a routine autopsy finding and ordinarily carries no clinical significance. Such adhesions are not detectable by physical examination and may or may not be seen in the x-ray as "tenting" of the diaphragm or thin shadows at the apex or in the interlobar fissures. These minor lesions are presumably the result of the minor episodes of dry pleuritis, which most persons have in association with one or more respiratory infections at some time during their lives.

Widespread and marked pleural thickening sufficient to interfere with pulmonary function is usually the end result of empyema or of tuberculous effusions. The physical signs resemble those of effusion in the presence of dullness and diminished breath sounds. However, the affected side of the chest is smaller than the normal opposite side, and the mediastinum is shifted toward rather than away from the disease process. In the earlier stages there may be a combination of extensive pleural thickening in some areas, with localized accumulations of fluid in others, and during this phase the mediastinum may be shifted in either direction, depending on which process predominates.

The distinction of pleural thickening from pulmonary atelectasis may be difficult or impossible by physical examination but will usually be resolved by the x-ray.

Advanced pleural thickening with or without calcification compromises the excursion of the affected lung and also interferes with bronchial drainage, thus promoting stasis and infection and favoring progressive pulmonary damage and further pleural injury. When the disorder is advanced, medical management is ineffective and decortication of the lung by an extensive surgical procedure, with resection of the diseased pleura, may be indicated. However, it is much better to prevent this disorder by the early recognition and proper management of empyema and of tuberculous effusions (pp. 893 and 1014).

Pneumothorax

Spontaneous Pneumothorax. This is a frightening emergency which often affects apparently healthy young men. There may be a history of some unusual exertion, but the rupture of the lung, ordinarily assumed to occur in a small subpleural bleb, usually does not accompany the exercise. Older patients with pulmonary emphysema are also prone to develop pneumothorax. In these individuals the

lack of retractive force of the lung may result in a collapse of only a limited extent. However, the gravity of pneumothorax in such patients is enhanced by the underlying limitation of pulmonary reserve and also by the avascular character of the pulmonary surface, with consequent slow healing of the leak. Spontaneous pneumothorax is occasionally seen in sarcoidosis, silicosis, and in miscellaneous fibrotic or infectious disorders of the lung; when rupture occurs through an infected area as in patients with tuberculosis, carcinoma, or lung abscess, *pyopneumothorax* or an infected *hemopneumothorax* usually ensues. Here the management must include that of the underlying pulmonary disease, and of the resulting empyema, as well as maneuvers designed first to prevent pleural scarring and later to restore ventilatory function. Persistent *bronchopleural fistula* is a common and distressing problem in such patients.

Tension pneumothorax consists of the progressive increment of positive pressure in the pleural space by a ball-valve action of the air leak. Deep, gasping inspirations, which are common in the anxious and dyspneic victim of a spontaneous pneumothorax, serve to aspirate large volumes of air into the pleural cavity. During expiration the leak becomes obstructed. Cyanosis is often intense, and failure to decompress the pleural space within a few minutes may result in death.

The diagnosis of spontaneous pneumothorax is suggested by sudden severe dyspnea with unilateral chest pain, usually pleuritic in character, plus tachycardia and shock in some patients. Physical findings may include cyanosis and displacement of the trachea and mediastinum as well as the classic signs of air in the pleural cavity. A small pneumothorax may be overlooked in the x-ray and may produce only minimal signs. Thus the physician must be skilled in physical diagnosis. Recognition of pneumothorax is especially treacherous in the presence of emphysema, which itself may cause wide flat interspaces, increased resonance, distant bronchial breathing, or absent breath sounds.

X-ray demonstration of pneumothorax is best obtained during full expiration which sharpens the contrast between the lung and the pleural air.

Spontaneous pneumothorax is often a recurrent disorder. Adhesions acquired as a result of spontaneous pneumothorax may prevent total collapse of the lung at the time of a subsequent episode. However, although dyspnea may thereby be lessened, these adhesions may increase the pain. In order to prevent recurrent pneumothorax, several operations have been devised, all of which depend on the production of pleural symphysis. Most satisfactory is probably the decortication of the pleura combined with resection of blebs. Opinion is divided concerning the number of pneumothoraxes

which should be permitted before these operations are attempted.

The management of a spontaneous pneumothorax with only slight retraction of the lung from the chest wall and minimal symptoms should consist in observation alone. When the findings are more compelling, a needle should be inserted immediately into the pleural space. If the pressure is positive throughout most of the respiratory cycle, which may be detected by observing the plunger to be blown back in the syringe, the latter should be removed until atmospheric pressure is attained. A thoracic pump or, if this is not available, an underwater trap is then attached.

Once the tension pneumothorax is controlled, the decision must be made whether tubes are to be inserted into the chest for further decompression or whether simple aspiration will suffice. Tubes attached to a pump should always be employed when there is a tension pneumothorax, when there is respiratory insufficiency, when there is fluid and therefore the likelihood of infection, and when there is a history of pneumothorax on the opposite side. Otherwise, a needle should be inserted and air aspirated until a mean negative pressure of 3 or 4 cm of water is attained. If, after a few moments of waiting, the pressure has crept back to an atmospheric level, the leak is still open and a tube should be inserted. If the pressure remains negative, the needle may be removed. From 12 to 24 hr later a needle is again inserted and the pressure again measured. If the lung has not leaked, the pressure will now be more negative than previously and as much air as possible should be removed. The remaining air is allowed to absorb. If, on the other hand, the pressure indicates continued leakage into the pleural space, one should not delay longer the insertion of a tube.

Hemothorax. Hemothorax or blood in the pleural space may accompany pneumothorax, as discussed above, may be associated with a broken rib, or may occur as a result of a neoplasm. Diagnosis may be aided by cytologic examination and by x-ray after removal of the blood, perhaps with instillation of air to demonstrate the pleural surfaces. If blood is allowed to remain, the likelihood of empyema and also of fibrothorax is increased. Ventilatory function is often preserved after traumatic hemothorax by early thoracotomy for decortication of the restricting layer of organizing thrombus.

DISORDERS OF THE MEDIASTINUM

Tumors and aneurysms within the mediastinum are discussed on pp. 1365 and 1563, respectively. All the disorders of the pleura may at times involve the mediastinal surfaces, and a collection of pleural

fluid lodged between the lung and the mediastinum may resemble a mediastinal mass.

Displacement. When a major bronchus on one side is completely obstructed, the mediastinum will move to the opposite side during expiration, remain there until inspiration, and then return. In partial bronchial obstruction the structures shift similarly during expiration but then begin to drift back toward the midline prior to inspiration. During inspiration the mediastinum is then pulled toward the obstructed side, but if the breath is then held at full inspiration, it drifts back to the center.

Other common causes of mediastinal displacement include (1) various types of chest deformity, (2) hydrothorax and pneumothorax, which push the mediastinum away from the lesion, and (3) atelectasis and pleural adhesions which pull the mediastinum toward the diseased side. Scars in the apex of the lung, such as in old fibrotic tuberculosis, may lead to sharp angulation of the trachea, with obstructive dyspnea.

Herniation. The parietal pleurae of the two lungs are in apposition in the anterior superior mediastinum and also in the posterior inferior (retrocardiac) area. At these sites the lung of a patient with bullous emphysema may herniate from one side far into the contralateral hemithorax.

Acute Mediastinitis. This may be associated with deep pharyngeal, thyroid, or cervical infection, with pyogenic pneumonia, and with many viral and rickettsial diseases. Retropharyngeal pain, aggravated by breathing, by extension of the head, and by yawning, is a common manifestation. The problems are analogous to acute pleuritis except that residuals of infection may obstruct the venous return, may damage the phrenic or recurrent laryngeal nerve, and may involve the pericardium.

Rupture of the esophagus which produces acute mediastinal necrosis and constitutes a grave emergency is discussed on p. 1589.

Spontaneous Mediastinal Emphysema. This condition may occur following rupture of a pulmonary alveolus, with dissection of air along the vessels and extension to the mediastinum. The tight retrosternal pain accompanied by venous distention and cyanosis may lead to an erroneous diagnosis of myocardial infarction. However, the pain is more likely to be sharply aggravated by breathing, a systolic popping, clicking, or crunching sound (Hamman's sign) is often heard, cervical subcutaneous emphysema may be present, and the x-ray may demonstrate air in the mediastinum.

Other causes of mediastinal emphysema include tension pneumothorax, thoracentesis, tracheotomy, thoracotomy, and pneumoperitoneum. The outlook is usually good, but rarely convulsions or even death from air embolism may occur. The likelihood of subcutaneous and mediastinal emphysema with

pneumothorax or following thoracotomy is greatly lessened by the use of the Emerson high flow, low pressure thoracic pump, emptying the pleural space through adequately large tubes.

DISORDERS OF THE DIAPHRAGM

Displacement. Because of the liver, the right hemidiaphragm is normally about 4 cm higher than the left. Upward displacement of a localized area may be caused by a subdiaphragmatic mass such as an abscess or by an adhesion within the thorax. Less commonly, it is the result of a congenital weakness of a small area of diaphragm. Upward displacement of both sides is common in disorders associated with high intraabdominal pressure, such as pregnancy, extreme obesity, or ascites. When the total lung capacity is reduced as with diffuse pulmonary fibrosis, the diaphragm may be pulled upward to its normal expiratory position. Conversely, the loss of pulmonary retractive force associated with emphysema causes an abnormally low position, and the liver may be palpable even though it is not enlarged.

Unilateral downward displacement results from pleural effusion. Occasionally, pleural fluid may collect entirely between the diaphragm and the inferior aspect of the lung, rather than in the lateral and posterior aspects of the pleural cavity, thus causing both physical examination and the x-ray to give the erroneous impression of a high position.

The diaphragm normally moves 4 to 10 cm with deep breathing. Scarring following empyema, hemothorax, or long-standing effusion not only limits excursion but may produce a fixed high position, simulating paralysis. Injury to the phrenic nerve results in variable degrees of elevation and reduced motion. The high completely paralyzed diaphragm moves paradoxically upward during quick inspiration. Partial injury to the phrenic nerve—which may be important in the evaluation of a mediastinal mass—sometimes can be detected only by fluoroscopic demonstration of a lag in the descent of the diaphragm during inspiration or a failure to move either way. The usual cause of phrenic paresis or paralysis is invasion by tumor; less frequent causes are mediastinitis or extensive scarring of the adjacent pleura. Therapeutic phrenic crush is now rarely done, but trauma to the nerve may occur with thoracic or cervical injury.

Singultus, or Hiccups. This is a quick involuntary contraction of the diaphragm with a closed glottis and may be of central origin, as in persons with encephalitis or brain-stem injury. More commonly, it appears to be initiated by reflexes arising from neighboring organs. Thus it may be present in patients with myocardial infarction, pneumonia, gastric distention, pancreatitis, or peritonitis. Pro-

longed singultus is exhausting and interferes with nutrition as well as with respiration. When gastric suction, antiemetic drugs, carbon dioxide breathing or rebreathing in a paper bag fail, the phrenic nerve may be anesthetized. The nerve also can be rendered refractory by rapid stimulation over its source in the neck, using an electrophrenic respirator.

Diaphragmatic Flutter. Diaphragmatic flutter is a rapid regular or irregular contraction of the diaphragm, continual or in paroxysms. It may be painful. The cause is usually obscure but in some instances appears to be hysterical. Often only a small portion of the diaphragm is involved, and if this area is on the left, the repetitive audible sound of the contraction may lead to an erroneous impression of cardiac arrhythmia.

Herniation. *Herniation of the abdominal viscera* through the diaphragm may occur in several locations, including the anterior substernal space (foramen of Morgagni), the pleuroperitoneal hiatus, and through defects in the posterior portion of the diaphragm near the esophagus. By far the most frequent site is through the esophageal hiatus itself (p. 1581). Fluoroscopic examination of the barium-filled stomach with the patient in the head-down position is the best means of demonstrating a diaphragmatic hernia. When a portion of the fundus of the stomach lies above the diaphragm, one must ascertain whether in addition an abnormally short esophagus is also present because of the more difficult surgical correction of this condition.

Eventration. Eventration of the diaphragm consists of an extreme upward displacement of a congenitally thin, often membranous, hemidiaphragm and must be distinguished from a large hernia or total absence of the hemidiaphragm since the surgical management is quite different. These disorders may cause digestive symptoms, dyspnea and cough, recurrent pulmonary infections, or may be asymptomatic. They may be suspected only when abdominal sounds are heard in the thorax of the recumbent patient, thus representing an exception to the rule that the sitting or standing position is best for physical examination. The diaphragm in eventration can often be seen, even though it is thin on the radiograph, but for a positive diagnosis one may have to instill a few hundred milliliters of air into the abdominal cavity and then determine by x-ray whether the air collects under the diaphragm or at the apex of the lung.

267 TUMORS OF THE MEDIASTINUM

Gustaf E. Lindskog

Mediastinal tumefactions may be classified according to their pathogenesis as follows: true neoplasms (e.g., thymoma), congenital malformations (e.g., bronchogenic cysts), infections (e.g., tuberculomas), and degenerative lesions (e.g., arterio-sclerotic aneurysms). True neoplasms may be primary or secondary and benign or malignant.

Within the narrow confines of the mediastinum even the most benign and slowly growing tumor can on occasion produce irreparable damage to the host by mechanical encroachment, compression, and obstruction of vascular channels, the esophagus, and the tracheobronchial tree. Infection may develop in cystic lesions from blood-borne sources or by direct extension after erosion into the bronchi or into the esophagus. A comprehension of mediastinal anatomy is therefore essential to the study of mediastinal tumors; furthermore, any attempt to define the pathologic nature of these lesions before surgical excision must lean heavily on their location in the mediastinal compartments, since the different varieties of tumor have definite sites of predilection (Fig. 267-1).

Anatomy of the Mediastinum. The mediastinum, as the name implies, is a space lying between the right and left pleurae in or near the median sagittal plane of the thorax. More for clinical purposes than for anatomic reasons, the mediastinum has been divided into four compartments: superior, anterior, middle, and posterior.

The superior mediastinum is bounded in front by the manubrium and behind by the upper four thoracic vertebrae. Inferiorly, it is demarcated by an imaginary line extending from the manubriogladiolar junction to the fourth vertebral body. This space contains the aortic arch and its major branches (innominate, left subclavian, and left com-

mon carotid origins), the innominate veins, and the upper half of the superior vena cava, the trachea, esophagus, thoracic duct, thymus gland, some lymph nodes, and the vagus, phrenic, left recurrent, and cardiac sympathetic nerves.

To be found in the superior compartment are bronchogenic cysts, tuberculomas, thyroid and parathyroid adenomas, teratomas, and metastatic tumors.

The anterior mediastinum is demarcated in front by the sternum, posteriorly by the pericardium, and below by the diaphragm. It is a very meager space and contains normally only some areolar tissue, lymphatics, lymph nodes, and branches of the internal mammary arteries.

In this space may be located teratomas, thymomas, lymphangiomas, and any of those listed for the superior mediastinal space.

The middle mediastinum comprises the heart and its pericardial covering, the ascending aorta, the lower portion of the superior vena cava and its junction with the azygos vein, the bifurcation of the trachea, the proximal pulmonary arteries and veins, the phrenic nerves, and some lymph nodes.

In this compartment may be found bronchogenic cysts and pericardial cysts or diverticula.

The posterior mediastinum is bounded in front by the heart, in back by the lower eight thoracic vertebrae and the shelving posterior portion of the diaphragm. It contains the thoracic descending aorta, the azygos and hemiazygos veins, the esophagus, the thoracic duct, the vagus and splanchnic nerves, and some lymph glands.

In the posterior mediastinal compartment are typically found neurogenic tumors and also certain bronchogenic, esophageal, and gastroenteric cysts.

Symptomatology. A majority of benign mediastinal tumors are asymptomatic and are discovered in the course of routine roentgenograms or those done for other purposes. With very few exceptions, symptoms are not specific and are caused by complications which include pressure necrosis, secondary infection, hemorrhage, and rupture of cystic lesions into a neighboring viscus. Thus fever, cough, dyspnea, wheezing, chest pain, and hemoptysis may occur in any combination and sequence. Dysphagia is not a very common symptom.

Malignant tumors which invade extensively in the mediastinum tend to produce the so-called *syndrome of the superior vena cava*. This is manifested by edema of the neck, face, and conjunctiva, together with distention and increased pressure in the veins of the neck, chest, and upper extremities. Epistaxis may occur, and also hoarseness from laryngeal edema or paralysis of the recurrent nerve. The patient may have severe headache, fainting spells, and vertigo. This syndrome sometimes occurs with very large benign tumors, such as thyroid

FIG. 267-1. A simplified lateral projection of the chest showing sites of predilection of various mediastinal tumefactions. (Courtesy, Dr. John Chapman.)

adenoma, located in the superior aperture of the thorax.

One pathognomonic symptom of a particular mediastinal tumor is *trichoptysis* or the spitting up of hair, usually accompanied by sebaceous material. This occurs in the case of dermoid cysts, but only when fistulization into the tracheobronchial tree has taken place.

Differential Diagnosis. Certain lesions originating in structures outside the mediastinum proper can intrude themselves secondarily and give rise to confusion in diagnosis. Such include (1) substernal goiter, (2) diaphragmatic hernias, (3) tumors arising in the thoracic skeleton, and (4) thoracic meningocele. In addition, aneurysms of the heart, aorta, and great vessels and pericardial effusion may simulate tumor.

Substernal goiter usually arises as a nodular downward extension from a lower thyroid pole. There may be a palpable mass in the neck; the trachea tends to be compressed and deviated away from the side of the lesion. Radiographic continuity of the mediastinal mass with a cervical thyroid shadow is commonly seen under fluoroscopy, most substernal goiters move freely and downward during deglutition, just as the normal thyroid gland does. Radioactive iodine tracer techniques may be useful in doubtful cases.

The diaphragmatic hernias most likely to be confused with mediastinal tumor are those located in the parasternal foramen of Morgagni. These may be essentially solid lesions consisting of herniated omental fat. In the lateral radiographic projection, they are based strictly in the anterior cardiophrenic angle. The air pattern of the transverse colon may be abnormally elevated; this can be further demonstrated by barium enema. Esophageal hiatal hernias also may present a homogeneous tumefaction in the lower middle mediastinum when the content of the hernial sac is principally omentum. A barium

swallow is therefore an important procedure with supradiaphragmatic lesions.

Chondroma, chondrosarcoma, and Ewing's sarcoma arising in rib or vertebra may grow internally and expansively in certain cases. Careful roentgenologic study of the involved bone should lead to the detection of some changes, but these may be quite inconspicuous. Pain is likely to be severe with malignant bone tumors and can simulate that caused by neurogenic tumors when it is segmental in type.

Thoracic meningocele is a very rare lesion seen chiefly in middle-aged women and associated with von Recklinghausen's disease (*café-au-lait* spots and multiple neurofibromatosis). Radiographic examination of the spine shows enlargement of several intervertebral foramina.

Aneurysms of the aorta and its major branches are of great concern in the differential diagnosis of mediastinal tumors. They are discussed in Chap. 247.

Large *pericardial effusions, pericardial cysts, and idiopathic cardiac hypertrophy* may be confused radiologically and clinically with mediastinal neoplasms. Chronic lymphadenopathy related, for example, to tuberculosis or fungous infection may produce mediastinal tumefactions readily confused with tumors. In the condition known as giant lymph node hyperplasia, discrete masses of thickly encapsulated lymphoid tissue may occur in the upper and anterior mediastinum and persist in the absence of any recognized infectious or malignant process. Some cases are associated with accumulation of plasmacytes and reticular cells.

In the lower posterior mediastinum, extramedullary hematopoiesis may result in a lobulated tumefaction large enough to be recognized radiographically.

Diagnostic Methods. Physical examination should include a careful study for enlarged peripheral lymph nodes, especially in the supraclavicular and axillary groups, and for splenomegaly and hepatomegaly in connection with the malignant lymphomas. Recurrent nerve paralysis should be ruled out by indirect laryngoscopy. *Horner's syndrome* is usually a stigma of malignant infiltration of the upper dorsal sympathetic chain, but may occur as a pressure effect from discrete and benign tumors. This syndrome is characterized by narrowing of the palpebral fissure, recession of the eyeball, a contracted pupil, and absence of sweating on the ipsilateral side of the face.

Bronchoscopy is rarely of definitive value in the diagnosis of primary mediastinal tumors but may be required to rule out lesions such as bronchogenic carcinoma. Bronchography employing iodized oil is neither helpful nor necessary unless obstructive complications in the lung require evaluation.

Sometimes the latter are at least as demanding of therapy as the causative tumor.

A complete radiologic study includes fluoroscopy, lateral and oblique roentgenograms, as well as the standard PA projection. A barium study of the esophagus should be carried out in every case of aneurysm and in the case of all tumors of the middle and posterior compartments. Laminagrams may be very helpful. The radiologist tries to determine, among other things, the presence or absence of encapsulation, the existence of calcifications, air and fluid levels, intrinsic or extrinsic pulsations, and the movement of the lesion during respiration and deglutition. Of greatest importance is the position of the lesion in the mediastinal compartments; characteristic locations are described under Anatomy.

Surgical excision of a cervical, axillary, or other enlarged lymph nodes may be of great diagnostic value particularly when such diseases as Hodgkin's, tuberculosis, and Boeck's sarcoid enter the differential diagnostic picture.

Even when lymph node enlargement is not detectable, it is sometimes possible to establish a tissue diagnosis after *en bloc* resection of the small lymph nodes in the fatty tissue overlying the scalenus anticus muscle near its insertion.

The commoner types of mediastinal tumors will be discussed briefly in terms of their special characteristics.

Teratoid Tumors. Benign teratoid tumors are commonly called dermoids. They are usually large when first recognized, ordinarily in the third and fourth decades. More often unilocular than multilocular, they contain sebaceous material and hair. Dental structures and bone are sometimes present and cause characteristic radiographic densities. The more complex teratomas are fleshy and contain tissue recognizable as nervous system, intestinal tract, pancreas, kidney or testis, and the like. The capsules may be ill-defined and infiltrated by carcinomatous or sarcomatous cells. A predominantly unilateral development may lead to confusion with such tumors as seminoma and chorionepithelioma. The complex teratomas have a very high incidence of malignant change with local invasion and metastases.

Bronchogenic, Esophageal, and Gastroenteric Cysts. These are developmental anomalies of the primitive foregut and bronchial buds. Commonly unilocular, they are chiefly located in relation to the trachea, upper bronchi, and esophagus; rarely they are found in the periphery of the lung or upon the diaphragm. Communication with the air passages may preexist or develop later because of pressure. The result is *pyocyst*, and this may be associated radiographically with an air-fluid level simulating pulmonary abscess.

The majority of these cysts have a respiratory type of epithelial lining with ciliated columnar cells and pseudostratified basilar nuclei; smooth muscle, cartilage, and mucous glands may be present. Squamous and gastrointestinal types of lining cells are occasionally encountered, principally in the cysts located about the distal esophagus. The gastrointestinal types are prone to give rise to serious symptoms in the first year of life, the others in adult life.

Neurogenic Tumors. Neurogenic tumors are the most frequently encountered of primary mediastinal neoplasms. Several pathologic types are recognized: (1) neurilemmomas, derived from the sheath cells of Schwann; (2) neurofibroma, a more complex but usually benign lesion showing, in addition to Schwann cells, neuraxones and proliferated connective tissue; (3) ganglioneuroma, with ganglion cells in variable stages of maturity interspersed in a stroma of neurofibromatous type; (4) sympathicoblastoma, derived from primitive cells which are small, round, densely nucleated, and with a tendency to pseudorosette patterns; (5) paraganglioma, including the rare hypersecreting variant, pheochromocytoma.

About 95 per cent of posterior mediastinal tumors are neurogenic in derivation, but neurilemmoma and neurofibroma may occur in a more lateral or peripheral situation in relation to the intercostal nerves. An expansile growth located in an intervertebral foramen may enlarge the latter as demonstrated in roentgenograms; by intrusion into the epidural space it can produce symptoms of spinal cord compression, the so-called "dumb-bell" tumor. Other histologic types of tumor, such as benign lipoma, may produce these same effects.

Ganglioneuromas exist principally in relation to the sympathetic chain and can produce the typical Horner's syndrome and sweating changes of the ipsilateral upper extremity. Neurofibroma may be a local manifestation of von Recklinghausen's disease.

Tumors of the Thymus. Tumors arising in the thymus gland are frequently difficult to identify and classify. The two main cell types, thymocyte (lymphocyte?) and reticulum (epithelial?) may be present in varying proportions. Thymomas tend to be heavily encapsulated and lobulated, fleshy or solid. Microcyst formation is common, but gross cystic changes can occur. Microscopically perithelial arrangement of tumor cells around vascular, lymphatic, or tissue spaces is rather characteristic. Hassall's corpuscles are found in only about 25 per cent.

Malignant change in a thymic tumor is signaled by capsular infiltration and invasion of contiguous structures, such as pericardium, trachea, large ves-

sels, and pleura. Remote metastases are uncommon even in fatal cases.

Thymic tumors are found in 15 to 20 per cent of myasthenia gravis cases, and a significant number of patients with thymic tumors on careful analysis are noted to have myasthenic symptoms. Thymectomy and excision of thymic tumors have an unpredictable effect upon the course of myasthenia gravis, ranging from cure to no effect.

Thymomas are known to occur in not infrequent association with aregenerative anemias, but the surgical ablation of the tumor, again, does not necessarily cure the hematologic disorder.

Other Generally Benign Tumors of the Mediastinum. Lipomas and fibromas are relatively rare. They occur anywhere in the mediastinum and furnish the largest specimens; some as heavy as 17 lb have been reported. Pressure symptoms are disproportionately mild.

Lymphangiomas are typically cystic and located in the anterior mediastinum and cardiophrenic angle. They are multilocular and demonstrate elastic tissue and smooth muscle in association with the mesothelium-lined channels. Cervical and mediastinal locations may be combined in the same case. Spontaneous chylothorax has been reported, and secondary infection, but ordinarily these are asymptomatic tumors.

Parathyroid adenomas usually occur in the expected distribution of the normal parathyroid glands. In perhaps 20 per cent of cases they are located ectopically in the mediastinum. Such adenomas are ordinarily quite small and are not often visualized by radiographic methods. An outline of the esophagus with barium may be helpful. The surgical treatment of hyperparathyroidism requires a complete search of the cervical area before the mediastinum is explored, ideally in a single operation.

Pericardial (Pericardiodiaphragmatic) Cysts and Diverticula. Aberrations in the development of the pericardial sac may lead to the formation of pericardial diverticula or cysts. These are unilocular, thin-walled sacs containing clear colorless fluid. A simple endothelium lines the thin connective tissue wall. Diverticula are rarer than cysts; they communicate by a narrow ostium with the main pericardial sac, whereas the cysts are separate and may even be at some distance from the pericardium. They produce no symptoms as a rule and are removed only for diagnostic purposes.

Primary Malignant Tumors. The lymphoblastic series of tumors (lymphoma, Hodgkin's disease, and lymphosarcoma) constitute about 70 per cent of this category. Various types of connective tissue malignancies also occur, such as fibrosarcoma. Epithelial neoplasms independent of any demonstrable extramediastinal focus (such as the peripheral

lung) are least common. Some of these rarities may arise from the thymus, from pharyngeal pouch remnants, or from degenerating teratoid lesions.

Hodgkin's disease (see Chap. 243) may begin in the mediastinal nodes and remain apparently localized there. More commonly, there is relatively early involvement of the cervical, axillary, or other peripheral lymph nodes; this enlargement may constitute the first clinical evidence of the disease. Splenomegaly occurs in about 70 per cent of Hodgkin's cases at some time in the course. There may be itching of the skin. Systemic manifestations such as periodic fever, malaise, anorexia, and weight loss are more common with Hodgkin's disease than with lymphosarcoma and reticulum cell sarcoma. The latter is sometimes confined to the region of the thymus when first recognized, only to spread later and produce the clinical picture of superior vena caval obstruction. Pleural effusion may develop.

Secondary Malignant Tumors. The commonest tumor of the mediastinum is undoubtedly metastatic carcinoma. The site of origin may be an intrathoracic organ such as esophagus, trachea, or bronchi. Mammary cancer is a frequent invader, however, and remote neoplasms such as renal and ovarian carcinoma may metastasize to lymph nodes and subsequently extend more diffusely in the mediastinal tissues.

Extension to mediastinal lymph nodes is an important limiting factor in the surgical treatment of mammary carcinoma. Its frequency has led to the recommendation that preliminary biopsy of the internal mammary chain of nodes be performed in cases where the primary breast lesion is situated in the medial quadrants, and when the axillary lymph nodes are palpably involved.

Isolated lymph node metastases in the mediastinum may be quite asymptomatic. As enlargement and infiltration occur, manifestations of pressure and pain may develop, and the syndrome of superior vena caval obstruction (p. 1500) is not infrequently observed.

Treatment of Mediastinal Tumors. Benign mediastinal neoplasms cannot be differentiated accurately by clinical and radiographic methods from localized malignant forms. Therefore, the indicated therapy is surgical exploration and excision, unless there exists some compelling reason to the contrary, such as extreme old age, or coexisting disease which itself has a lethal prognosis.

The most useful exploratory incision is a long posterolateral one with rib resection, since technical problems may be considerable. Certain anterior tumors can be reached by median sternotomy or parasternal chondrectomy. Ideally the tumor should be totally extirpated in a single stage.

Certain large and infected cystic tumors in poor-risk patients may be marsupialized for drainage and resected at a later date.

The mortality rate for excision of benign and localized malignant mediastinal tumors is less than 5 per cent and in some reported series approaches zero.

Invasive malignant neoplasms can only be biopsied or partially resected. An attempt should be made to recognize these unfavorable cases by careful physical examination and to obtain tissue for microscopic study by simple techniques such as needle biopsy and the like. When these fail, a mediastinotomy may be required. It is important not to treat a suspected lymphoma or other mediastinal neoplasm by radiation until a tissue diagnosis is established. There are many pitfalls in so-called diagnostic radiotherapy.

Hodgkin's disease confined to a local area should be treated with heavy doses of radiation, and in a rare case this may be combined with surgical excision. Widely disseminated tumors must be palliated with smaller doses of roentgen rays and such chemotherapeutic agents as the nitrogen mustards.

268 THERAPY OF RESPIRATORY INSUFFICIENCY

Eugene Robin and
John H. Knowles

The numerous physiologic defects present in chronic pulmonary disease have already been discussed (pp. 104 to 124). Regardless of etiology, these defects are found to a greater or lesser degree in most forms of chronic pulmonary disease. Effective therapy must obviously be based on an understanding of the physiologic aberration present and should be guided by the fact that the defects due to infection, excessive secretions, bronchospasm, and alteration of the blood gases are potentially reversible. The physiologic abnormalities and their therapy are considered below. Generally the discussion applies to chronic bronchitis and obstructive emphysema, the commonest forms of chronic pulmonary disease.

AIRWAY OBSTRUCTION

Airway obstruction in chronic pulmonary disease results from the presence of thick, viscid respiratory tract secretions; from bronchial edema, from bronchospasm, from bronchial or peribronchial fibrosis; and from parenchymal destruction with the development of bronchiolar check valves.

Secretions. The patient with chronic pulmonary disease commonly suffers from hypersecretion of mucus in the tracheobronchial tree, which leads to chronic cough, dyspnea by virtue of airway obstruction, and recurrent infection. He may be unable to dispose of such secretions because of ineffective mechanics of coughing and inadequate ciliary activity. The first principle of treatment is the avoidance of irritants, the chief offender being tobacco smoke. Complete cessation of smoking should be advised. Careful inquiry into the presence of noxious environmental gases and dusts, both at work and in the vicinity of the patient's home, must be undertaken. A change of job or home might be indicated. Similarly, a change of climate, from one with wide swings of temperature and humidity to one which is warm and dry the year around, may be beneficial if the patient can undertake the financial and emotional burden of moving. A trial period in the chosen area should precede the patient's final decision.

Periodic increase in cough and in the volume of secretions is commonly due to superimposed bacterial infection, particularly during the winter months (see also below). Both cough and sputum production may be markedly diminished by full courses of the appropriate antibiotic dictated by the result of sputum culture.

During periods of acute infection, secretions may become particularly thick, tenacious, and viscid (in addition to their volume increase) and therefore difficult to remove. The sputum of the ambulatory patient without obvious infection may have similar characteristics, although in lesser degree. Measures to liquefy the sputum should be employed in either instance. The inhalation of warm, moist air (steam) is probably the single most effective measure in decreasing sputum viscosity. Other measures include close attention to the general hydration of the patient; the use of iodides orally or parenterally; the use of detergents by inhalation ("Aleva-vaire," which consists of glycerin, sodium bicarbonate, and Triton A-20) to lower sputum viscosity; and the attempted enzymatic digestion of sputum by the inhalation of aerosolized enzymes such as trypsin (Tryptar) or pancreatic dornase. Iodides are the most effective measure and are usually given as saturated solution of potassium iodide, 10 drops by mouth, three or four times a day. Definite evidence is lacking that the use of detergents and enzymes aids measurably in the removal of secretions except for the resultant local hydration *per se*. In addition, the enzymes may give rise to considerable local irritation of the pharynx. In a small number of patients with chronic pulmonary disease, the volume of secretions is so excessive that drugs, such as terpin hydrate or guaia-col, that diminish the amount of sputum may be usefully employed.

Special measures designed to assist in removing secretions may be necessary. In the patient who is not acutely ill, a consistent program of postural drainage may be helpful, particularly if the volume of secretions is continuously large. The patient should be carefully instructed in the proper technique of performing postural drainage. During its performance the patient should assume the head-down position, the prone position, right and left lateral decubitus, and the sitting position, so that all lobes are drained. Coughing in explosive style during drainage should be avoided, to prevent further lung damage. During acute respiratory infections, postural drainage may not suffice; mechanical removal of secretions is then necessary. This may take the form of tracheal suction by means of a soft catheter passed through the naso- or oropharynx. If this is not successful in the emergency situation, therapeutic bronchoscopy may be required. Finally, if none of the above measures is effective, or if they are of only transient benefit in the severely ill patient, a tracheostomy may be necessary for the purpose of frequent and efficient suctioning of secretions. Tracheostomy also decreases the respiratory dead space, thereby facilitating improvement in the level of alveolar ventilation. Exact in-

dications for tracheostomy are difficult to outline. Certainly, inability to control secretions by more conservative methods is one indication. Continued deterioration despite intensive therapy is another indication. Such deterioration may be defined by either clinical criteria or by a rising arterial CO_2 tension. The patient with severe pulmonary insufficiency, who is about to undergo thoracic surgery, may be considered as a candidate for prophylactic tracheostomy. In general, if any doubt exists as to the necessity for this procedure, it should be resolved by having the procedure performed. Preferably then, if indicated, the tracheostomy should be instituted early rather than late, should be done in a slow, unhurried manner, and should be performed in the operating room rather than at the bedside.

After the tracheostomy, a number of precautions are necessary to prevent complications. To avoid infection, tracheal suction should be performed with sterile precautions and disposable catheters. To prevent trauma to the tracheal mucosa, the catheter should be moistened before use. A T-tube arrangement should be placed in the suction line so that negative pressure is applied only when the catheter has been positioned inside the lumen of the trachea. The catheter should not be vigorously thrust up and down within the tracheal lumen. The patient's head should be turned to the right and left during suction, so that the left and right main-stem bronchi can be reached. If available, a curved catheter for entering the left main-stem bronchus is desirable. To prevent hypoxia, hypercapnea, and fatigue, suctioning periods should be limited to 15 to 30 sec at a time. The use of very high expiratory flow rates to dislodge retained secretions (exsufflation with negative pressure) has been of value in some patients with postoperative atelectasis, but only rarely in those with chronic pulmonary disease.

Decreased Cross-sectional Area of the Bronchial Tree. The degree of reversible luminal narrowing of the bronchial tree due to bronchospasm and bronchial edema varies widely from patient to patient. It is not sufficiently appreciated that many patients with chronic obstructive ventilatory disease have a component of bronchospasm as a factor in their airflow obstruction. This may be impossible to detect clinically. For this reason, the routine use of bronchodilators is useful in the therapy of chronic pulmonary disease. Their use need not be entirely empiric. The 1-sec timed vital capacity or maximal midexpiratory flow rate should be determined before and after the inhalation of aerosolized bronchodilator and any increase noted.

The drugs may be administered orally (ephedrine, 15 to 25 mg three or four times a day, usu-

ally combined with 15 mg phenobarbital), rectally (0.5 Gm aminophylline suppository at bedtime), by aerosol inhalation [1:200 isoproterenol hydrochloride (Isuprel) or 2.25 per cent racemic epinephrine hydrochloride (Vaponephrin)], or parenterally (intravenous aminophylline). (Parenteral epinephrine is not ordinarily used in the older patient with chronic lung disease as it is in bronchial asthma.) The aim of therapy is to relieve bronchospasm for as much of each 24 hr as possible. For this reason, bronchodilators should be administered on a consistent schedule, and around the clock, if possible; the dosage should be increased during periods of increased bronchospasm.

Corticosteroids may be useful in the control of bronchospasm and bronchial edema in some patients. In the life-threatening situation, they may be used empirically if the condition does not respond to the usual measures outlined above and a reversible bronchospastic element is suspected. Similarly, in the occasional patient with chronic pulmonary disease whose clinical state suggests the possibility of bronchial asthma or at least a large reversible obstructive element which is not improved by the usual therapy, a diagnostic and therapeutic trial with corticosteroids may be indicated. Careful evaluation by serial test (e.g., timed vital capacity) is necessary to determine the ultimate need for such therapy. The hazards of peptic ulceration and reactivation of pulmonary tuberculosis must be recognized in such patients.

Since it has been demonstrated that cigarette smoke and other respiratory tract irritants produce an increase of resistance to airflow, cigarette smoking should be interdicted and the patient removed from exposure to irritant fumes to whatever degree possible.

More difficult to treat than the functional decreases in bronchial cross-sectional area are those based on anatomic damage to the bronchial tree or its loss. One major factor in this form of respiratory tract obstruction is that the application of high positive pressure across the thorax tends to collapse bronchioles and, hence, increases the degree of obstruction. Breathing exercises teach the patient to prolong expiration using lower intrapleural pressures. Pursed-lip breathing—pursing the lips and making an "F" sound on expiration—is taught. Expiration is made an active, prolonged effort; active use of abdominal muscles is stressed. The pressure gradient across the thoracic cage is lessened, and the amount of air trapping and of airway resistance due to early closure of bronchioles is decreased. The inhalation of gas mixtures that are less dense than air (80 per cent helium 20 per cent oxygen) may decrease the resistance to turbulent flow, although resistance to laminar flow may be increased because the mixture is more viscous than air.

HYPOXIA

Hypoxia in patients with chronic pulmonary disease may result from generalized alveolar hypoventilation, from regional hypoventilation, or from a decrease in the diffusing capacity of the lung. Aside from measures designed to produce an overall increase in total ventilation and to improve regional hypoventilation by decreasing airflow resistance, the most effective measure in therapy of hypoxia is the inhalation of oxygen-enriched mixtures. The inhalation of high concentrations of oxygen will produce an increase in the alveolar tension of oxygen in all ventilated alveoli (i.e., those that are not totally occluded). The increase in alveolar oxygen tension will be reflected in an increase of oxygen tension in the pulmonary-capillary blood supplying these alveoli and will ultimately be reflected in an increased tissue oxygen supply (provided cardiac output remains constant). Oxygen administration also permits an adequate supply of oxygen at a minimal work cost of breathing to the patient. This factor tends to decrease the over-all oxygen consumption of the patient and may partially explain the decrease in dyspnea that occurs during oxygen inhalation. Oxygen-enriched mixtures may be supplied by nasal catheter, oxygen tent, face mask, or by means of an intermittent positive-pressure apparatus. The exact technique of administration will depend on individual circumstances. The oxygen stream must be kept moist to prevent drying of the respiratory mucosa and secretions. This may be accomplished by bubbling the oxygen through properly warmed water.

In some patients with extremely severe pulmonary disease with acute or chronic hypercapnia and hypoxemia, there may be a loss of the normal respiratory center responsiveness to CO_2 -pH stimulation, presumably because of narcotic levels of CO_2 tension in the blood. In such patients the ventilatory drive appears to depend chiefly on impulses arising from the chemoreceptors of the aortic and carotid bodies, which respond chiefly to hypoxemia. Removal of the hypoxemic drive by means of oxygen inhalation may result in increasingly severe hypoventilation with a precipitous rise in arterial blood CO_2 tension and drop in pH. Drowsiness and disorientation occur, and in severe cases convulsions, coma, and even apnea ensue. In such patients, oxygen administration must be carefully controlled. However, it should be emphasized that the relief of profound hypoxia is essential in the treatment of such patients. The problem, therefore, is not whether they should be treated with oxygen but how to treat them with oxygen and maintain ventilation while doing so. The dilemma may be resolved in one of several ways. It may be possible to wean the patient back to the continuous use of

oxygen by giving it intermittently at first, or in concentrations less than 100 per cent (e.g., a 40 per cent oxygen mixture; or reduction in the flow rate of 100 per cent oxygen given by nasal catheter). If these measures are unsuccessful, mechanical ventilators are necessary in patients developing life-threatening hypoventilation during oxygen administration.

RESPIRATORY ACIDOSIS

The basic mechanism producing respiratory acidosis is always inadequate alveolar ventilation. Such inadequacy may result from an over-all decrease in ventilation or from severe regional hypoventilation of sufficient magnitude so that CO_2 , being produced metabolically cannot be disposed of in adequate amounts. Carbon dioxide retention may be treated by two general techniques: (1) reduction of the amount of CO_2 being produced metabolically, and (2) increased CO_2 excretion by the lungs.

The following techniques are available for reducing CO_2 production:

1. Reduction in the work cost of breathing. In normal subjects the work cost of breathing amounts to less than 2 per cent of total metabolism. In patients with chronic pulmonary disease, this value may increase to as much as 40 per cent. Indeed, it has been suggested that the CO_2 cost of breathing may be so high in some patients with chronic pulmonary disease that further increase in ventilation actually causes a rise and not a fall in CO_2 tension. The measures which have been outlined above result in more efficient ventilation and, hence, in a decreased work cost of breathing.

2. Reduction in physical activity. Obviously a reduction in over-all activity will result in a decrease of metabolism. Such reduction in activity during periods of acute illness is usually provided by hospitalization. In nonacute periods, the avoidance of severe overexertion and periodic rest intervals may help to accomplish the same purpose.

3. Reduction of total metabolism by means of induced hypothyroidism. Radioactive iodine administration has been employed in an effort to induce some degree of hypothyroidism in patients with chronic pulmonary disease and in this manner to limit their metabolic requirements. This approach is as yet experimental and has not enjoyed widespread use. The unpleasant symptoms and appearance of hypothyroidism may be intolerable to the patient and his family.

The following techniques are available for increasing CO_2 output by the lung:

1. Improving the ventilatory status of the lungs by removal of secretions, treat

and the liberal use of bronchodilators, as outlined above.

2. Attempted stimulation of the respiratory center by drugs in order to induce hyperventilation. Such drugs as Coramine, progesterone, and Vandalil are capable of increasing alveolar ventilation. In general, these drugs have limited usefulness because regardless of central drive, the degree of hyperventilation is limited by the underlying abnormalities of the peripheral ventilatory mechanism, i.e., the disease of the lungs and thoracic cage. The same is true of the use of salicylates and acetazolamide (Diamox).

In this regard it is useful to point out that one of the most important aids in restoring respiratory center sensitivity is to improve the blood gas composition by elevating ventilation. Either increasing oxygenation or reducing CO_2 retention (or both) of the arterial blood may result in resumption of rhythmic and efficient respiratory movement in the patient nearly apneic with uncoordinated respiratory muscle activity. It is mandatory to withhold any drugs, such as morphine, Demerol, and the barbiturates, that are capable of accentuating respiratory center depression.

3. In the acutely ill patient, assisted ventilation by means of one or another type of mechanical ventilator offers the best method of increasing alveolar ventilation and decreasing CO_2 tension, thus increasing the excretion of CO_2 . A number of different respirators are available. The one most commonly used at present employs intermittent positive pressure (IPPB). With this apparatus the lungs are periodically inflated by means of positive pressure and expiration takes place passively. Such apparatus also provides facilities for the humidification of inspired air and for the administration of bronchodilators in the form of aerosol deep into the tracheobronchial tree. This type of apparatus is generally designed so that it may be actuated by the patient's own respiratory efforts or may function automatically in the patient whose spontaneous respiratory drive is not sufficient to maintain ventilation.

There is no general agreement on the value of IPPB as a routine measure in the day-to-day treatment of patients with chronic obstructive disease. Some workers believe that such therapy has great value in increasing alveolar ventilation, and others feel that it may represent a potentially useful technique for administering bronchodilator aerosols.

COR PULMONALE

The treatment of this complication is considered in some detail on p. 1539. The problem is basically that of the vigorous management of both congestive

heart failure (Chap. 219) and of pulmonary failure, as discussed above.

INFECTION

Because of the difficulties of proper drainage of secretions, the problem of recurrent infection in patients with chronic pulmonary disease is serious. Either frankly pathogenic organisms or bacteria of relatively low virulence, such as *Hemophilus influenzae*, may be responsible. Severe pulmonary infection may occur in this group of patients without the usual systemic indications such as fever or leukocytosis. For this reason early and vigorous chemotherapy is important. Such chemotherapy should be guided by careful bacteriologic examination. Less well established is the use of prophylactic chemotherapy during infection free periods. This problem is currently under study. It should also be reiterated that postural drainage, bronchodilators, and steam inhalation are important adjuncts to the therapy of recurrent pulmonary infection.

SURGICAL THERAPY

The operative treatment of chronic pulmonary disease involves the excision of blebs and bullae which have compressed normal lung. Resection of such lesions allows adjacent normal lungs to expand and, depending on the size and location, will allow greater excursion of the diaphragm and relieve distortion of the mediastinal contents. The poorest results are achieved when a severe degree of underlying obstructive emphysema exists which has accounted for the dyspnea and disability experienced by the patient. Indications and contraindications for the removal of cysts have been discussed on p. 1557.

Direct approach to the problem of obstructive pulmonary emphysema per se has centered on surgery of the autonomic nervous system and on efforts to increase the blood supply of the lung. Dorsal sympathectomy, vagal denervation, dissection of perivascular and peribronchial tissues, and parietal pleurectomy with talc poudrage have all been tried, alone or in combination. The evidence is slim that any of these maneuvers gives lasting benefit to subjects with chronic pulmonary disease, and the hazards involved do not usually justify the attempts.

The use of pneumoperitoneum and of abdominal binders, in the hope of increasing the excursion of the diaphragm by upward displacement, has largely been abandoned.

THE ACUTE RESPIRATORY EMERGENCY

A number of different diseases may produce such interference with the process of ventilation that the

patient's life is threatened by the resultant hypoventilation or apnea. Under these circumstances, artificial maintenance of ventilation is mandatory. The initial step is to ensure a patent airway. The patient's neck should be hyperextended and, if available, either an oropharyngeal airway or, preferably, a cuffed endotracheal tube inserted. While equipment is mobilized, adequate ventilation may be maintained by means of mouth-to-mouth breathing. As soon as possible, suction should be performed to clear respiratory secretions. Artificial ventilation over a prolonged period can be successfully carried out by a number of techniques. One commonly employed method uses an intermittent positive-pressure apparatus (IPPB). This apparatus is powered by compressed air or oxygen. The lungs are inflated by positive pressure and deflate passively. Preferably, the instrument should have an automatic cycling device so that if the patient's respiratory efforts are too feeble to trigger the mechanism, ventilation will continue. Also desirable in such instruments are independent controls for the regulation of air flow and pressure, so that these parameters may be tailored to the patient's requirements. All such apparatus provides means of humidifying the inspired gas before it reaches the patient. Another commonly used variety of respirator is the piston type (Moersch), in which fixed volumes of moistened and heated air or oxygen are driven into the lung by means of a piston powered by a motor.

Ventilation may also be accomplished by means of a tank (Drinker) respirator. The patient's body (except for head and neck) is enclosed in a chamber, in which subatmospheric and supraatmos-

pheric pressures are generated to produce volume flow of air into and out of the patient's respiratory tract.

As indicated above, when cough or swallowing is impaired, tracheostomy should be performed for the control of secretions.

Meticulous attention to hydration, electrolytes, care of bowel and bladder, infections, and orthopedic and psychologic problems is required. The patient's survival frequently depends on the degree of excellence of the nursing care provided.

Section 5: The Alimentary Tract

269 GENERAL CONSIDERATIONS

Franz J. Ingelfinger

The evaluation of gastrointestinal complaints is becoming harder and knottier as the diagnostic techniques available become more numerous and intricate. This paradox, in view of the contributions made to the diagnosis of gastrointestinal disorders by roentgen rays, biochemistry, and endoscopy, may be challenged as hyperbole, but it sets in focus a disturbing question: To what extent is diagnosis today a human or mechanical function? The problem is particularly acute for the physician

trying to diagnose an abdominal disorder. Aware of human error, and his confidence circumscribed because he must decide on the condition of viscera that he often can neither see nor feel, the physician turns for help to the laboratory or the machine, to which he imputes an unwarranted objectivity and accuracy. The more elaborate and complex the technical method, moreover, the more the ordinary physician is unaware of its limitations, and the more he stands in awe of the results it bears. Thus any student or physician preparing himself to handle gastrointestinal problems (or any medical problem for that matter) must decide whether it is better to run or to be run by a technology that is superb but strange to him. Put in another way, he

must decide between a purposefully eclectic and routinely comprehensive approach.

The comprehensive routine is the method of the survey: it rigorously pursues an unvarying check list of questions, orders a complete "battery" of laboratory tests and extensive radiologic studies, viz., pyelography, cholecystography, upper gastrointestinal series, and barium enema. The routinely comprehensive approach thus provides automatic safeguards, it protects against ignorance, negligence, and forgetfulness. It also detects the unexpected: the colonic polyp, for example, in the patient whose symptoms of heartburn direct attention to the esophagus and stomach. It even permits the physician—if he orders blood calcium determinations (at \$5 a test) routinely—to exhibit a somewhat spurious serendipity in finding the rare patient with hyperparathyroidism among the many patients with digestive complaints.

An elevated serum calcium level, however, does not necessarily signify hyperparathyroidism; it may be the result of vitamin D intoxication, of excessive milk-alkali therapy, or perhaps merely of laboratory error. The trouble with the routine mill is that its products—whether hypercalcemia, an x-ray report of diaphragmatic hernia, or the patient's insistence that certain foods give her indigestion—tumble forth in haphazard and unrelated fashion. So unrelated, indeed, are the results that it makes little difference if x-rays or history are obtained first, and adherents of the comprehensive survey might indeed perform more efficiently by reversing the usual sequence. Eventually, of course, all the findings have to be assembled into a meaningful whole, but it takes time to put together a jigsaw puzzle, and completion of the picture is easily prevented by a big piece which does not fit but which seems important because it originated in the laboratory or in the x-ray dark room.

The eclectic method uses the chief complaint to orient the line of study and then purposefully proceeds to elicit points of information specifically designed to support or to weaken the various diagnoses possible. This means that the chief complaint immediately should suggest a list of differential diagnoses. Historical data, physical findings, x-rays, and laboratory examination are thereupon sought and analyzed to create a framework that has meaning at all stages of its development. As points of information become available, they are evaluated for significance on the basis of their interrelationship: do they make sense within the diagnostic framework being erected? Or perhaps they are sufficiently cogent to undermine its foundations and thus to necessitate a new start. In the end, the structure created should form a compact and reasonable whole with as few extra pieces lying around as possible.

The gastrointestinal complaints of many a patient are in great part determined by the kind of individual he is. Ulcerative colitis flourishes in individuals of certain emotional make-up and family background, psychologic stress intensifies the symptoms of sprue, and the anxious cancerphobe fearfully mulls over the meaning of her aerophagic belching. A knowledge of the patient's character is therefore highly desirable, and it is obtainable only by conversation. Thus, a careful and purposeful exploration of the chief complaint, performed with a full realization of the close interrelationship of psyche and gut, almost automatically provides the physician with the character insight he needs to handle his patient not only sympathetically but also effectively.

THE INTERPRETATION OF SYMPTOMS

Pain of all varieties, ranging from vague discomfort to excruciating colic, is the most common of digestive tract symptoms. To distinguish such pain from painful conditions of other organs, its location and quality serve some purpose; but the prime consideration in deciding whether or not abdominal, thoracic, or back pain is of alimentary tract origin is its relation, or lack of relation, to some gastrointestinal function. Thus the man with colonic pain may experience relief after passing gas or stool, or he may feel worse, or a desire to defecate may accompany his distress. If a patient has esophageal pain, its incidence and intensity are usually related to swallowing. In other instances, the relationship is less obvious and depends upon interpretive use of medical knowledge, as, for example, in the case of the patient with duodenal ulcer who has pain at times when his gastric pH may be assumed to be at its lowest.

Correlation between a pain and a gastrointestinal function must of necessity be chronologic and hence susceptible to the fallacies of *post hoc-propter hoc* reasoning. A meticulous inquiry as to the frequency, specificity, and chronology of the relationship serves, however, to reduce the likelihood of error. When the patient says, as he so often does, that "the pain comes on after meals," find out exactly when (while eating dessert, immediately after finishing, within 15 min. or later, while at work or watching television); find out after what meals and how often after given meals. Such questioning the heart of the eclectic method, serves not only to determine the degree and nature of the relationship between eating and pain, but also helps to distinguish the organic from the functional complaint. The man with cancer of the esophagus or duodenal ulcer has relatively little difficulty in describing the chronologic relationships of his complaints, but

the person with functional complaints¹ cannot be pinned down. A relationship between meals, particularly between certain kinds of foods and symptoms, may be vigorously claimed by the patient with functional disorders, but lawyer-like cross examination reveals a witness who cannot describe consistent or specific relationships.

Caution is of course also necessary. Some digestive tract pain, as from pancreatic cancer, for example, may appear totally unrelated to any alimentary tract activity. Conversely, copious eructations after meals may mark the pure neurotic or the man with serious coronary insufficiency. Renal colic may wear the costume of paralytic ileus, and endocrine disorders may present as abdominal pain with deranged bowel habits. Such pitfalls and exceptions notwithstanding, the rule stands: gastrointestinal pain usually has something to do with gastrointestinal function.

Nausea and vomiting are such frequent manifestations of all kinds of diseases—or of injudicious therapy—that their relatively limited significance as symptoms of digestive tract disease deserves emphasis. If some cases of gastric retention are excluded, painless nausea and vomiting (the "painless" is crucial) do not indicate major disease of the alimentary tube, gallbladder, or pancreas. Much more likely to be responsible are functional disorders, central nervous system disease, cardiovascular-renal disease, endocrine abnormalities, or drugs. Painless nausea and vomiting, of course, are frequent symptoms of hepatic disorders

INTERPRETATION OF REPORTS FROM THE LABORATORY, THE RADIOLOGIST, AND THE ENDOSCOPIST

Whether the average physician attempting the diagnosis of a gastrointestinal complaint uses the eclectic or routine approach, he depends for help on the specialized skill of others and must accept, perforce, the results of a serum transaminase determination, a gastroscopy, or a barium enema at their face value. The problem presented by the x-ray examination of the gastrointestinal tract is particularly troublesome. With the knowledge, skill, and technical facilities now in his hands, the expert radiologist can detect a host of variations from normal, and as is his duty, he reports them. If the physician

¹ "Organic" and "functional" are frequently used words, but with nuances and implications that vary from user to user. To the author, an organic disease is one with recognizable structural changes. A functional disorder is literally a disorder of function, a change in "how an organ works." According to this view, functional is a descriptive term, not etiologic. Thus a functional disorder, e.g., simple constipation, may or may not be psychogenic in etiology.

receiving these reports makes diagnoses by using the comprehensive survey method, if his x-ray requests are not dictated by a specific diagnostic question, he is apt to be overwhelmed. After all, here is a report in black and white of something clearly pictured in white and black. His unorganized clinical investigation offers little resistance, and the x-ray report becomes the final diagnosis by subtle metamorphosis. Thus the patient's real trouble may be relegated or even obliterated by the x-ray findings. A combination of x-ray findings may, indeed, be confused with clinical syndromes, and the patient in whom the astute radiologist finds a coexistence of gallstones, diaphragmatic hernia, and diverticulosis may be portentously diagnosed as suffering from Saint's triad, a "syndrome" which from the clinical viewpoint is unadulterated nonsense (If among women aged fifty or more, gallstones occur in 20 per cent, diaphragmatic hernia in another 20 per cent, and diverticulosis in 50 per cent, a combination of these conditions will unavoidably exist in two out of every 100 such women examined.)

The physician with the eclectic approach is better prepared. Having a diagnostic pattern in mind, he tests the fit of laboratory, x-ray, endoscopic, cytologic, and biopsy findings. If the fit is bad but the finding weighty, he does not insist on his clinical judgment; he is well aware, for example, that a vague and nonspecific clinical picture in no way contravenes an x-ray diagnosis of gastric cancer. On the other hand, he also knows that x-rays are not infallible, and if a patient has typical ulcer symptoms or a classic history of biliary colic, the physician does not permit his clinical case to collapse merely because of a negative x-ray report. Nor is he necessarily content with the diagnosis of diaphragmatic hernia in a patient who has a radiologically demonstrated hernia and unimpressive electrocardiographic findings, but who gives a history of squeezing substernal distress coming on with exercise and promptly relieved by rest or nitroglycerin.

Exceptions and atypify confuse the path, but to reach correct gastroenterologic diagnosis most consistently, it pays to insist (1) that gastrointestinal symptoms and gastrointestinal function evidence some interrelationship, (2) that the clinical picture and the results of technical diagnostic procedures jibe, and (3) that all information, whatever its source and nature, create a reasonable whole.

EVALUATION OF TREATMENT

Some years ago, an English physician named Gill treated 20 patients with gastric ulcer by giving them a daily injection of 1 ml of sterile water. As

judged by gastroscopic criteria, the ulcers healed in 4 to 8 weeks, the time usually required under conventional therapy. In a study organized on statistical principles, Doll, Jones, and Pygott observed the rate of gastric ulcer healing in three groups: nonsmokers, smokers who continued to smoke, and smokers who stopped smoking. Decrease of ulcer size by two-thirds or more was attained within 28 days in 75 per cent of the smokers who stopped smoking, as opposed to 58 per cent of those who did not stop; but the proportion of nonsmokers showing comparable ulcer healing was also 58 per cent, i.e., no better than the results obtained in the unregenerate. Such observations highlight the problem of rational treatment of gastrointestinal disorders. Except in cases where surgical intervention is either mandatory or highly effective (e.g., appendicitis, cholelithiasis with biliary colic, intestinal obstruction, ulcerative colitis refractory to medical treatment), the specific effects of therapeutic procedures, whether medical, dietary, or surgical, are assessed with great difficulty.

Enthusiasm, of course, may run high, and the medical literature is swollen by reports vigorously advocating this or that treatment. The fact remains, however, that if surgical procedures and specific infections and infestations are excluded, no gastrointestinal condition exists that is susceptible to dependably curative medical management. To be sure, symptomatic or partial improvement is possible. Elimination of gluten arrests the steatorrhea in many cases of idiopathic sprue, stretching the gastroesophageal junction decreases the dysphagia of the patient with cardiospasm, intensive neutralization of gastric juice heals the peptic ulcer, and adrenocortical therapy may induce remission in ulcerative colitis, but these methods provide alleviation, not cure of the condition. In the case of more vaguely defined entities, gastritis and irritable colon, for example, the efficacy of any therapeutic endeavor is even more difficult to evaluate.

These points are not meant to inculcate a pessimistic attitude toward gastrointestinal therapy. They do mean, however, that the student or the practitioner of gastroenterology must maintain an objective attitude concerning the regimen he advocates. If he insists on rigid dietary injunctions, he should have some rationale beyond reliance upon routine practice. When antacids are prescribed, he should have some reason for prescribing an elaborate (and expensive) concoction of aluminum hydroxide, magnesium salt, sedative, and a so-called antispasmodic, as opposed to giving much cheaper and often equally effective calcium salts and tincture of belladonna. In deciding on an anticholinergic agent, he should be aware of exactly what such agents may do to gastrointestinal motility and

secretion and that these agents are not necessarily beneficial under all conditions. A potent anticholinergic, for example, may reduce the volume of gastric secretion, but this possibly beneficial effect may be offset by the increased gastric retention that also results from vagal inhibition. Furthermore, the claims that synthetic anticholinergic agents are so selective that only the gastrointestinal tract is affected must be judged in the light of evidence suggesting that individuals vary tremendously in terms of dose response and that, as of the moment, specific gastrointestinal effects without side effects are more of a hoped-for ideal than an accomplished fact.

The patient with gastrointestinal complaints obviously requires therapy, but in view of the uncertain state of many of the measures employed, a number of generalizations are offered to guide treatment along an honest path.

1. To the extent that treatment is nonspecific, the art of medicine becomes important. Thus the care, sympathy, and enthusiasm with which treatment is administered clearly influence the results.

2. Traditional treatment is tested by experience and hence safe in the eyes of the public and the medical profession. By and large, it is also safe for the patient, but not always so, as, for example, the not-so-old practice of forcing large amounts of protein on the semistuporous patient with advanced liver disease. Thus the alert physician, aware of the deficiencies of traditional gastrointestinal treatment, may use its principles as a therapeutic base line but is constantly looking for and receptive to new approaches.

3. Before a new regimen or approach is used, it deserves analysis. A new medicine should obviously not be employed merely because it is new ("the latest development") and insistently distributed by its maker. If a new method is recommended in the medical literature, the basis for such recommendation is examined with profit. Is it rational in terms of what is known concerning gastrointestinal physiology, pharmacology, and pathology? Has the investigation of the new treatment's efficacy been distinguished by adequate control studies with proper checks on the subjective influences of the investigator? Is there real evidence that the new method or agent is better than existing methods?

The generalizations made concerning treatment are of course not peculiar in their application to gastroenterology. On the other hand, the fact that treatment of gastroenterologic conditions is so limited to a symptomatic plane makes such treatment highly susceptible, on one hand to hasty innovations and ill considered enthusiasms, and on the other to stubborn adherence to practice sanctified by no more than tradition. The best thing a physician can

do to avoid these extremes is to ask himself, as he instructs the patient, "Why am I doing this?"

270 DISEASES OF THE MOUTH

E. Cheraskin

Significant diagnostic information can be obtained from simple inspection of the oral cavity. This is possible because the mouth is a very sensitive barometer of systemic balance.

Oral symptoms and signs fall into two groups. Some of these findings are highly characteristic, though generally not pathognomonic, of a specific disease state or a family of disorders. Others reflect, through nonspecific clues, simply the presence of chronic disease.

SPECIFIC ORAL FINDINGS OF SYSTEMIC DISEASE

The oral symptoms and signs of about 50 systemic disorders are characteristic enough to warrant special mention. These conditions include the active participation of biologic agents, chemical intoxication, hormonal imbalance, nutritional deficiency, developmental factors, and the lack of adaptation to stress.

In the main, the oral clues may be divided into the following categories: (1) pigmentation, (2) ulceration, (3) salivary changes, (4) dental pathosis, and (5) miscellaneous findings.

Pigmentation. Congenital leues is characterized by red or copper-colored necrotic crusts on the lips which, with healing, leave linear scars radially arranged and perpendicular to the mucocutaneous junction (rhagades). Thrush is noted by a soft, painless, pearly-white elevated patch. Some of the common viral diseases are associated with oral signs. Koplik's spots are blue-white specks surrounded by a red border on the buccal mucosa just opposite the maxillary first molars. These lesions appear about 24 to 48 hr prior to the onset of the rash of measles. Occasionally, one may observe early in mumps, inflammation of the buccal mucosa surrounding the opening of Stensen's duct. Characteristic yellow to gray palatal papules, 2 to 20 in number, which form vesicles and quickly rupture

may be observed in herpangina. Gingival and palatine petechiae have been described in infectious mononucleosis. Argyria is associated with generalized mucosal darkening and possibly a violet line at the free marginal gingiva. Bismuthism, mercurialism, thallotoxiosis, and plumbism all show a pigmented line in the free gingival margin. With cadmium intoxication there is a yellow to gold ring about the cervixes of the teeth. The most suggestive oral finding of Addison's disease is generalized mucosal melanin pigmentation. The tongue in many of the vitamin B-deficiency states may become red or magenta. One of the highly characteristic findings in pernicious anemia is the red inflamed dorsum of the tongue. In the Peutz-Jeghers syndrome, there are often melanin macules upon the lips, buccal mucosa, tongue, and hard palate. Wickham's striae (thin white strands of lacelike arrangement on the buccal mucosa) are considered typical of lichen planus. Finally, primary or secondary polycythemia may be recognized by the generalized deepening of the color (blue-red) of the entire oral mucosa.

Ulceration. The two most common extragenital sites for the luetic chancre are the lips and tongue. Secondary syphilis is recognized by oral mucous patches. A cardinal sign of agranulocytosis is pleomorphic dirty-gray or black ulcers which are not surrounded by the erythematous margin that is generally observed bordering most oral ulcers. Riboflavin, nicotinic acid, and pyridoxine deficiency can contribute to the development of angular cheilosis.

Salivary Changes. Sialorrhea (an increase in saliva) is commonly associated with arsenism, bismuthism, mercurialism, thallotoxiosis, plumbism, and cadmium intoxication. An increase in salivary flow has also been described with cretinism and vitamin B-deficiency states. On the other hand, sialorrhea is encountered with hyperthyroidism, diabetes mellitus, Sjogren's disease, and hereditary ectodermal dysplasia.

Dental Pathoses. In about one-third of the cases of congenital syphilis, Hutchinsonian incisors and mulberry molars are present. Slight to moderate enamel chalkiness which becomes exogenously pigmented is fairly common with chronic fluorosis. When hyperactivity of the anterior lobe of the hypophysis commences early in life, the end result (gigantism) may include generalized macrodontia. On the other hand, the oral picture of the acromegalic patient shows macroglossia, prognathism, and malocclusion. Hypophyseal dwarfism demonstrates delayed exfoliation of the primary teeth, retarded eruption of the permanent dentition, possibly microdontia, and commonly malocclusion. In the cretin, there is macroglossia, retarded eruption of the permanent teeth, and delayed exfoliation of the

primary dentition as well as malocclusion. Loosening of the teeth and disappearance of the lamina dura, as observed in the roentgenogram, are sometimes seen with hyperparathyroidism. In the case of hypoparathyroidism, there is enamel hypoplasia and possibly delayed eruption; the lamina dura, however, remains intact. With vitamin A deficiency there is sometimes enamel hypoplasia. One very glaring clue of Cooley's anemia is malocclusion of the medial open-bite type, where the teeth posteriorly are in contact but are not in occlusion anteriorly. This is due to maxillary overdevelopment. Osteogenesis imperfecta is notable for the opalescent color of the teeth. In addition, the crowns are disproportionately larger than the roots and the pulps are completely obliterated at an early age. Cleidocranial dysostosis may be recognized by a reduced number of teeth, lack of dental eruption, and the presence of a host of unerupted malformed teeth. Finally, a reduction in the number of teeth is a cardinal sign of hereditary ectodermal dysplasia. The developing teeth of the child with erythroblastosis fetalis may show a yellow to green endogenous pigment. Juvenile rheumatoid arthritis frequently includes destruction of the growth centers in the mandibular condyles. Hence, the end result is underdevelopment of the mandible, leading to severe malocclusion. Serial roentgenographic study of the jaws of the sclerodermic patient will disclose periodic thickening and thinning of the periodontal membranes. A fairly constant observation in mongolian idiosyncrasy is malformation or absence of the maxillary lateral incisor.

Miscellaneous Findings. In scarlet fever the fungiform papillae become enlarged (raspberry tongue). Sometimes there follows desquamation of the papillary tips (strawberry tongue). The most common oral stigma of tertiary syphilis is palatal perforation secondary to gumma formation. Fungi may invade the mouth. Actinomycosis is often recognizable by a yellow, purulent, granular drainage. Diphenylhydantoin (Dilantin) frequently results in the development of a painless, mulberry-shaped gingival hyperplasia. Fine tongue tremor is included in the classical description of hyperthyroidism. Hyperkeratosis is now regarded as sometimes indicative of a vitamin A deficiency. Thickening of the tongue and reduced lingual activity are observed frequently in patients with scleroderma.

NONSPECIFIC ORAL FINDINGS

More common, if not as dramatic, are the nonspecific oral symptoms and signs. These do not provide the examiner with immediate clues to a specific systemic problem. However, they do supply evidence of chronic debilitation.

Oral Symptoms. A number of symptoms are peculiar to the oral cavity by virtue of its special structural design. Included in this group are gingival tenderness, xerostomia (dry mouth), and stomatopyrosis (burning mouth). The presence of this triad usually signifies a metabolic disturbance. For example, these three oral symptoms occur earlier and with greater regularity than polyphagia, polydipsia, and polyuria in the patient with diabetes mellitus. As a matter of fact, as evidence of their relationship to metabolic imbalance, these three oral symptoms may signify hypo- as well as hyperglycemia, and both hypo- and hyperproteinemia.

Oral Signs. Significant, though nonspecific, information can be derived from the presence of gingival bleeding and clinically demonstrable tooth mobility. Gingival bleeding occurs in approximately two-thirds of the population. Though it is usually attributed to faulty toothbrushing, there is the strong possibility that it may be a measure of increased vascular fragility and permeability.

Under physiologic conditions, the teeth are not clinically mobile. Clinical tooth mobility is a sensitive measure of metabolism. For example, it appears in the presence of carbohydrate, protein, and vitamin imbalance. Thus, clinical tooth mobility may be the first expression of diabetes mellitus, scurvy, protein deficiency, and the vitamin B-complex syndrome.

Oral Roentgenographic Findings. In the physiologic state, the alveolar bone should extend almost up to the cervix of the teeth. Alveolar bone loss occurs with defective osteoid matrix formation (osteogenesis imperfecta, protein and ascorbic acid deficiency, alarm syndrome), reduced matrix mineralization (rickets and osteomalacia), and increased bone resorption (hyperparathyroidism).

271 DISEASES OF THE ESOPHAGUS

Franz J. Ingelfinger

Although the anatomy of the swallowing tube is still controversial, the structural definitions indicated in Fig. 271-1 are used in this discussion. The esophagus proper, with principally propulsive func-

tions, is regarded as lying between two sphincteric segments at its upper and lower ends. The upper segment comprises the cricopharyngeus muscle and the highest circular muscles of the esophagus. The lower sphincteric mechanism is believed to lie in the upper part of the vestibule. It normally remains closed except during swallowing and regurgitation, and acts, in conjunction with the diaphragm and a possible flap-valve mechanism provided by the angle of His, to prevent gastroesophageal reflux. Compression of the intraabdominal portion of the vestibule by intraperitoneal pressure may provide another barrier against reflux.

Symptomatology. Dysphagia. Although esophageal disease accounts for no more than one-tenth of all gastrointestinal complaints, it is characterized by one of the most specific symptoms in medicine: the sensation of food sticking on its way from the mouth to the stomach. This dysphagia of esophageal origin can usually be distinguished from oropharyngeal dysphagia, which is characterized by inability to move a bolus out of the mouth, by nasal regurgitation, or by tracheal aspiration. Esophageal dysphagia, since it occurs only with swallowing, also differs from the persistent sensation of globus hystericus. Esophageal dysphagia may be painless, more often it is distressing, and sometimes it causes pain of alarming proportions. Whatever its concomitants, the complaint of food sticking somewhere behind the sternum signifies that some process—whether functional spasm or organic stricture—is occluding the esophageal lumen.

The level of the sticking sensation, corresponding to the most frequent site of esophageal disease, is usually under the lower end of the sternum. In other instances dysphagia is localized higher in the chest or at the base of the neck, either because the responsible lesion is situated higher or because sensations from the distal esophagus are referred to the sternal notch by approximately one-fourth of adult patients.

Dysphagia occasionally begins abruptly and reaches maximum intensity at the onset, but more commonly it appears gradually in intermittent attacks precipitated by the ingestion of certain foods. Beef and fresh bread are notorious offenders, probably because these elastic solids are wedged by peristalsis into the esophageal area narrowed by disease. If this happens, the patient may be able to force the offending morsel past the obstructing point by rapidly gulping water or may be able to regurgitate it by forceful retching. With progressive disease, however, the swallowing of liquid as well as solid becomes difficult. Liquids of low viscosity, as a matter of fact, are regurgitated too readily, and the peristaltic action of the esophagus is used to best advantage when the patient takes food of pultaceous consistency.

FIG. 271-1. Diagrammatic representation of the structure and relations of the lower esophagus. A. Normal esophagus. B. Paraesophageal hernia. C. Sliding hernia. In this type of hernia the distinction between the vestibule and the herniated cardia is lost, and the angle of His has become obtuse. P.E.L. = phrenoesophageal ligament. The location of the gastroesophageal junction is a matter of opinion. It may be defined as located at the level where the tube of the esophagus widens into the sac of the stomach, but sometimes the transition from one shape to the other is gradual rather than abrupt. Alternatively, the junction is placed at the serrated line where squamous esophageal and glandular gastric mucosae meet, but this epithelial boundary may be located somewhat above the level of the angle of His and thus does not necessarily coincide with a division of stomach and esophagus based on gross shape and muscular function.

Pain. Pain, a common symptom of esophageal disease, may be persistent and unrelated to swallowing or intermittent and intimately associated with dysphagia; often it is precipitated by the ingestion of acid, spicy, carbonated, very cold, or very hot substances. The mechanisms underlying esophageal pain are two: (1) ulceration or inflammation of the mucosa, and (2) increased intramural tension produced by violent peristalsis or stationary muscular spasm. Esophageal pain is usually felt anteriorly under the sternum at a level corresponding to the position of the lesion, but it may also be referred to the upper back, the neck, the jaws, and into both arms, particularly their inner aspects. Anatomically and functionally, therefore, the transmission and reference of pain from the esophagus and from the heart may be the same.

Heartburn. Heartburn, pyrosis, and water brash mean different things to different people, and it is important to determine what heartburn signifies to the patient with this complaint. Here the term heartburn is used to denote an intermittent symptom complex which begins with a burning, tight sensation under the sternum, and then travels upwards, wavelike, to reach its scalding, acid maximum in the neck or throat. Salivation is often part

of the picture. The cause of heartburn may be muscular spasm, reflux of gastric contents, or both, but its exact pathogenesis is still uncertain.

Belching. Many a belch is forceful regurgitation of air that has been sucked or swallowed into the esophageal lumen. Although belching, therefore, is frequently an esophageal phenomenon, it is, except in diaphragmatic hernia, not a common manifestation of esophageal disease. More often it is a functional disorder or is indicative of gastric, cardiac, or biliary tract disease.

Regurgitation. Regurgitation, as opposed to vomiting, means the effortless appearance of esophageal or gastric contents in the mouth. A functional disorder of gastroesophageal motility, a retrograde flow of material forced by normal esophageal peristalsis against a stenotic area, or as in the case of the dilated esophagus of cardiospasm, a gravitational effect may be responsible for regurgitation.

CANCER

Symptoms. The importance of dysphagia as a symptom and the urgent necessity of determining its cause are no better exemplified than by the patient with esophageal cancer. Difficulty in swallowing is often the patient's first, and at times his only, complaint as the growth encroaches upon the lumen. Although intermittent initially, the dysphagia is inexorably progressive over the course of months. In fungating tumors, the commonest gross variety of esophageal cancer, pain under the sternum, in the back, or in the neck, is usual and sometimes precedes dysphagia. In some cases an early symptom not to be ignored is substernal burning on swallowing hot liquids. Slow oozing of blood is a frequent complication, and brisk bleeding a rare one. In about 25 per cent of cases, however, particularly with infiltrative or polypoid cancers, symptoms other than dysphagia appear only terminally. When esophageal stenosis is severe, regurgitation of esophageal contents, sometimes blood-flecked, is common.

Approximately 20 per cent of esophageal cancers are in the upper third, 30 per cent in the middle, and 50 per cent in the lower third of the organ. The lesions in the upper two-thirds are derived from squamous esophageal mucosa. In the distal esophagus over half the cases prove to be adenocarcinomas, indicating that many cancers in this area are gastric in origin. A gastric origin is, as a matter of fact, often evident on operation in cases which radiologically appear to be purely esophageal.

Course. Physical examination is usually negative and even those patients with advanced disease may present no more than the signs of malnutrition. Although metastases to lymph nodes occur in three-fourths of the cases, only 5 per cent have palpable

nodes in the supraclavicular or other accessible areas. Since the liver and lung are each involved eventually in 20 to 25 per cent of the cases, hepatomegaly or pulmonary lesions may be evident. Other organs subject to metastatic foci are bone, kidneys, and adrenal glands. Sometimes direct invasion of adjoining structures leads to dramatic complications: (1) mediastinitis with subcutaneous emphysema in the neck, (2) tracheo- or broncho-esophageal fistula, with an apoplectic cough induced by swallowing liquids, or (3) aortic perforation with precipitous exsanguination.

Diagnosis. Esophageal cancer occurs in the usual cancer age groups, and males preponderate 4:1. It is about one-tenth as common as cancer of the stomach in either sex. X-ray often reveals the irregular and sometimes surprisingly long luminal defect caused by esophageal cancer, but supplemental diagnostic information must usually be sought by esophagoscopy with biopsy. The initial examination with either procedure is not, however, invariably adequate in differentiating cancer from inflammatory stricture. In these cases, cytologic examination of material obtained by esophageal lavage is indicated. This procedure yields 75 per cent positive results in patients with esophageal cancer.

Treatment. Lesions that appear to be resectable are usually treated surgically. Calculated on the basis of all esophageal cancer patients who enter a hospital, the 5-year cure rate is still a disappointing 0 to 7 per cent. In some hands, however, 5-year cure rates in patients who at operation have no gross evidence of extension are over 30 per cent for cancers in the lower third of the esophagus. Successful resection of higher cancers is more difficult. In patients with inoperable tumors of the fungating variety, palliation of dysphagia may be achieved to a remarkable degree by deep radiotherapy delivered by high voltage x-ray apparatus and Co⁶⁰ bombs.

DIAPHRAGMATIC HERNIA

A common abnormality affecting the esophagus but, strictly speaking, of gastric origin is herniation of the stomach through the esophageal hiatus of the diaphragm. Two types of hernia are described. In one, the paraesophageal or para-hiatal type, the gastric cardia rolls through the muscular aperture beside a gastroesophageal junction that is still normally situated with respect to the level of the diaphragmatic hiatus (Fig. 271-1B). In the other, the sliding, axial, concentric, or short esophagus type, both the stomach and the gastroesophageal junction slip up into the chest, thereby placing the gastroesophageal junction above the diaphragmatic hiatus (Fig. 271-1C). This position of the junction makes the esophagus appear shortened, and actual

shortening may be caused by chronic esophageal inflammation. A congenitally short esophagus, however, is rare. Many hernias are mixed in that they present features of both types.

The incidence of diaphragmatic hernia is debated, since its radiologic differentiation from a prominent vestibule is a matter of individual interpretation. In elderly persons, the incidence of sliding hernia exceeds 50 per cent, men appearing to be somewhat more susceptible; paraesophageal hernia, predominantly a disorder of women, is only one-tenth as common. Both types of hernia are more prevalent in stocky and obese individuals.

Symptoms. Both paraabdominal and sliding hernias may give rise to symptoms when the herniated pouch is irritated or injured by the mechanical disadvantages of its position or when it is sufficiently large to affect adjoining viscera. These complications characteristically affect the paraesophageal variety of hernia. The most common complaint is high epigastric or low midthoracic pressure or a pain which may radiate along the left costal margin, to the top of the left shoulder or down the arms. Belching is copious and hiccoughing occasional. By and large, the symptoms are moderately distressing, but a rare case may suffer acute prostration should strangulation of the herniated stomach take place. If the mucosa of the hernia becomes eroded, acute or chronic blood loss is possible, but the importance of diaphragmatic hernia as a source of gastrointestinal blood loss is usually exaggerated. Large hernias rarely cause intermittent acute dysphagia by angulating, twisting, or compressing the esophagus, or they may sufficiently displace the lungs or heart to cause cardiorespiratory symptoms. Whatever the clinical manifestations of diaphragmatic hernia, they are characteristically precipitated by eating and aggravated by lying down, both of which actions tend to force more of the stomach into the thoracic cavity.

The principal complication affecting sliding diaphragmatic hernias is peptic esophagitis. This is discussed below.

Diagnosis. Diagnosis is made by radiologic means. Once a diaphragmatic hernia is radiologically identified, however, its relation to the patient's symptoms poses a nice problem. On one hand, the symptoms of diaphragmatic hernia are so diverse that they may resemble the symptoms of coronary insufficiency, biliary colic, pancreatitis, gastric or duodenal ulcers, esophageal diseases, or functional digestive disorders. On the other hand, diaphragmatic hernias are diagnosed so frequently by the radiologist that many hernias must be considered as incidental findings unrelated to the patient's complaints. As a rule upper abdominal or lower thoracic symptoms should not be ascribed to a radiologically demonstrated diaphragmatic

hernia unless (1) other possible causes are excluded with reasonable certainty and (2) some evidence exists that the symptoms are intensified when the patient eats or lies down. A particularly difficult problem in differential diagnosis is sub-sternal distress in the elderly patient with both electrocardiographic abnormalities and diaphragmatic hernia. Although coronary pain is usually related to exercise and that of hernia precipitated by lying down, these associations are not constant, and both conditions may be aggravated by a full meal. When the evidence is conflicting, the wiser course is to assume that coronary disease is the principal offender.

Treatment. Most patients can become fairly comfortable but not entirely symptom-free by eating small meals of low fat content (fat retards gastric evacuation), by avoiding food entirely for 3 hr before going to bed, and by sleeping with the upper half of the body elevated. Additional symptomatic relief may be afforded by sedatives and antispasmodics. Weight loss is imperative for the obese. With respect to surgery, sliding hernias with esophagitis present a special problem, which is discussed later. Operative repair of paraesophageal hernias is indicated if they have been identified as causing intermittent esophageal obstruction, respiratory disease, perforation, strangulation, repeated or chronic bleeding, or severe distress not affected by intensive use of medical measures. If surgery is risky because of age or other illness, symptoms can be partially controlled by crushing the left phrenic nerve to paralyze the left diaphragm.

ACUTE ESOPHAGITIS

Acute esophagitis in a mild form, with sub-sternal pain aggravated by swallowing, may complicate upper respiratory infections. More violent forms with variable necrosis may occur in moribund states, in diseases of the central nervous system, after extensive burns or trauma, after operations, especially if vomiting is pronounced or gastric intubation prolonged, and with specific infections such as scarlet fever, diphtheria, typhoid, and viral diseases with herpetic oral lesions that extend into the esophagus. Monilial esophagitis may appear in those weakened by chronic disease, especially if antibiotics or adrenocortical therapy has been used. In many of these conditions, debility, ischemia, the trauma of vomiting, or exposure of the esophageal mucosa to acid gastric contents must be important pathogenic factors.

The ingestion of alkaline corrosive agents produces a classic variety of acute esophagitis which, if not immediately fatal, may terminate in extensive esophageal stenosis. Immediate treatment depends

on giving parenteral analgesics as needed for pain and antibiotics (e.g., aqueous penicillin, 600,000 units, and streptomycin, 250 mg. intramuscularly, four times daily for an adult) for fear of an impending mediastinitis. Oral intake is avoided for 3 to 7 days. After approximately one week, if no extraesophageal infection is apparent, adrenocortical therapy in full doses is recommended to contain the tissue reaction believed responsible for the ensuing stricture. The use of intubation is controversial; if undertaken, it should be performed by expert and cautious hands; the corroded esophagus is easily lacerated.

CHRONIC PEPTIC ESOPHAGITIS

Chronic esophagitis is an inflammatory reaction of the esophageal wall with erosions or frank ulceration of the mucosa and narrowing of the lumen by muscular spasm and fibrotic stricture. Although the etiology of some cases is obscure, the great majority are the result of excessive reflux of acid gastric juice. Peptic esophagitis and the acid-peptic factor appear to be causally related since the disorder occurs predominantly in those with high gastric acidity, is more common in males, and is associated in over one-third of the cases with former or concurrent duodenal ulcer. The abnormality that permits the excessive reflux is usually a sliding diaphragmatic hernia, which obtunds the flap valve created by the angle of His and eliminates both the intraabdominal segment of the vestibule and whatever contribution the diaphragmatic hiatus makes toward maintaining the competence of the normal gastroesophageal barrier (Fig. 271-1C). Occasionally a chronic esophagitis makes its sudden and discouraging appearance in an elderly patient following a severe vomiting episode or after intubation has been used as a postoperative measure or to treat gastrointestinal distention. In these cases, debility and local trauma presumably enhance esophageal susceptibility to refluxed gastric material.

Symptoms. The patient may or may not have had a past history of duodenal ulcer, but almost invariably he has been a long sufferer from heartburn. At first this symptom troubles the patient only after overeating, soon after retiring to bed, or when bending over. Intermittently and progressively, however, the heartburn worsens, cold and hot foods and slightly acid foods are increasingly painful to swallow, and eventually dysphagia appears. With advancing disease, malnutrition is inevitable and slow blood loss occasional.

Diagnosis. Diagnosis is made principally by x-ray, which in cases with stricture shows a gradual and funnel-shaped narrowing of the distal esophagus. The esophagus appears shortened and terminates

in a tentlike supradiaphragmatic projection of the stomach characteristic of a sliding hernia. Early cases, with minimal x-ray findings, may be recognized by the fiery, oozing, and mucus-flecked appearance of the distal esophagus seen through the esophagoscope. Patients with esophagitis are also apt to experience typical pain within 30 min when 0.1 N hydrochloric acid is dripped into the esophagus at a rate of 100 drops per minute (Bernstein acid test). The normal esophagus is said not to be sensitive to this procedure, but care must be taken to differentiate esophageal pain from any gastric pain that might be elicited by the acid drip. In the differential diagnosis, cancer, cardiospasm, diffuse spasm, and scleroderma must be considered. In the attempt to exclude cancer, examination of cells obtained by biopsy, esophageal washings, or both is essential.

Treatment. Medical management aims to protect the esophagus, reduce gastric acidity, and prevent gastric reflux. To protect the esophagus, the patient takes 1 tbs of a liquid, viscous antacid preparation, such as an aluminum hydroxide gel, at hourly intervals between meals while he is awake. The medication is taken "straight" and not followed by other material. To enhance its viscosity and emollient properties, the antacid gel may be mixed with 1 tsp of a vegetable oil. If pain is marked, additional symptomatic relief is achieved by giving an aluminum hydroxide gel containing a surface-active anesthetic such as oethazine. Anticholinergics are as a rule not indicated, since any advantage they might gain by reducing gastric secretion is offset by their disadvantageous action of increasing gastric retention as well. A bedtime anticholinergic is, however, reasonable for those who suffer nocturnal heartburn. A moderately bland diet is desirable, but more important is the avoidance of large meals at all times, and of any food or drink after the evening meal. In stocky or obese patients, weight loss is beneficial since abdominal fat may increase the degree of gastric herniation and reflux. Finally, 6- to 8-in blocks are placed under the head of the bed to lessen nocturnal gastroesophageal regurgitation.

Medical management of peptic esophagitis may relieve esophageal pain and the dysphagia produced by edema and spasm, but it is ineffective when dysphagia is caused by fibrous stricture. This must be treated by cautious dilatation. If dysphagia persists or recurs in spite of medical measures and dilatation, surgical intervention is indicated. In an early case, repair of the sliding hernia may be sufficient, but in most instances some type of operation designed to reduce gastric acidity (subtotal gastrectomy, vagotomy with a drainage procedure) is carried out at the same time. Such surgical effort is unfortunately not much more than 75 per cent

successful. Resection of the involved area, as may be necessitated by uncontrollable stenosis, is also not too rewarding; since all barriers to gastric reflux are removed, recurrence of esophagitis proximal to the gastroesophageal anastomosis is likely. Progress is being made in overcoming this difficulty by replacing the resected gastroesophageal section with a segment of small or large bowel.

PEPTIC ULCER

A solitary peptic ulcer is occasionally found in the distal esophagus. This lesion differs from peptic esophagitis in that the ulcer is more sharply localized, penetrates more deeply, and is more apt to perforate or to cause massive bleeding. On the other hand the ulcer is more susceptible to standard medical antacid management (Chap. 272), produces less extensive stricture on healing, and causes less chronic dysphagia than peptic esophagitis. The solitary peptic ulcer in the distal esophagus thus resembles a benign gastric ulcer in many respects. Indeed many ulcers at the lower end of the gullet actually involve either a herniated portion of stomach or a section of the esophagus—perhaps the vestibule—that is lined with gastric mucosa.

CARDIOSPASM (Achalasia)

The term *cardiospasm* does not describe the nature of the disorder accurately but is well established by custom. Actually cardiospasm is a motor disorder involving the entire distal two-thirds of the esophagus. In the esophagus above the vestibule, the normal propulsive pattern of peristalsis is replaced by nonprogressive and uncoordinated contractions. For this reason the name *aperistalsis* is used in Brazil. The massive esophageal dilatation seen in some cases has, in turn, given rise to the name *megacosophagus*. Finally, the term *achalasia* (literally, "not relaxation") is popular because the lower esophageal sphincter, i.e., the vestibular area, does not relax normally in response to swallowing and thus creates an obstructing segment at the distal end of the esophagus.

The motor disorders of cardiospasm appear to reflect an impaired cholinergic innervation of the esophagus. Histologically the cells of the myenteric plexus, i.e., the parasympathetic ganglions, are damaged or absent. Pharmacologic studies have shown that administration of a cholinergic agent produces a tetanic, specific, and often violent contraction of the affected esophagus. This response, when interpreted in the light of Cannon's finding that denervated structures respond maximally to neurohumoral stimulation, provides additional evidence that the cholinergic innervation of the esoph-

agus is deficient in cardiospasm. The ultimate etiology, however, is unknown. In Brazil, the remarkable prevalence of cardiospasm in areas where Chagas disease is endemic has fostered the strong conviction that the intrinsic esophageal denervation is a late result of esophageal infestation by the responsible agent, *Trypanosoma cruzi*.

Symptoms. Cardiospasm affects all ages of both sexes. Its course is usually chronic, with dysphagia gradually worsening over months to years. In some patients, the process is painless; in others spasms of substernal pain may follow eating. Occasionally the initial episode of dysphagia appears with dramatic suddenness, either after bolting food or after an emotional upset. In either case, however, the condition has probably been present in latent form before the acute episode. As the disease progresses, extreme and tortuous dilatation of the esophagus may develop. When the patient lies down, the copious amount of food residue, saliva, and other secretions contained in the spacious esophageal sac runs freely back into the pharynx and mouth. If the regurgitated material is aspirated, chronic infection of the lung bases is a potential complication. Stagnation of food also leads to a chronic inflammatory reaction of the esophageal mucosa and submucosa. Obviously, weight loss is common.

Diagnosis. Diagnosis is usually made without difficulty on the basis of the history and the characteristic radiologic findings of abnormal esophageal motor function with a smooth, beaklike narrowing of the distal esophageal segment. In some cases, cancer originating in the gastric cardia, but infiltrating the esophagus, may present a somewhat similar x-ray appearance, and a variety of motor disorders of the lower esophagus has been confused with cardiospasm. These problems in differential diagnosis should be less frequent if it is remembered that the radiologic abnormalities of cardiospasm consist of deranged peristalsis as well as narrowing in the area of the vestibule.

Treatment. Medical treatment, symptomatic at best, consists of the use of sedatives and bland, semisolid foods warmed to body temperature. Smooth-muscle relaxants such as nitrites are often used to open the vestibule, but the effect is too transient to permit the patient to enjoy a meal. Anticholinergics may lessen oral and esophageal secretions and may inhibit painful spasms; in view of the basic neurologic defect, however, they potentiate rather than alleviate the dysphagia. The best available therapy is forceful dilatation of the narrowed vestibule, with the specific purpose of tearing some of the muscle fibers in this area. Passing graduated mercury-tipped bougies does not accomplish this and therefore relieves dysphagia only briefly. It is necessary to use bags that can be inflated under pressure or a mechanical

(Starek) dilator. In experienced hands, these instruments, when positioned under fluoroscopic control, rarely cause complete esophageal rupture, and dysphagia is relieved successfully for years, or even permanently, in over 75 per cent of cases. Forceful dilatation does not restore normal esophageal motility, but it impairs the contractile power of the vestibule and thus permits the esophagus to empty under the influence of hydrostatic and transmitted oropharyngeal pressures. Improved esophageal emptying, in turn, prevents further esophagitis and distention of the lumen.

When the esophagus is extremely dilated and sufficiently tortuous to warrant the adjective *sigmoid*, mechanical dilatation of the narrowed area is often not feasible. Surgery is then necessary. Unfortunately any procedure that creates a new opening between the dilated esophagus and the stomach permits, when the patient lies down, reflux of gastric contents into an already damaged esophagus which cannot muster the peristaltic force necessary to return the gastric contents where they belong. The consequence is severe esophagitis, often more distressing than the cause of the operation and a major source of blood loss. If technically feasible, the surgical procedure favored at present is the Heller myotomy, which is based on the same principle as forceful dilatation: the contractile power of the vestibule is destroyed by placing a longitudinal cut through the muscle, but not the mucosa, of the narrowed segment. Myotomy is, however, not invariably successful in alleviating dysphagia or preventing reflux esophagitis. In advanced cases, with unsuccessful previous operative procedures, jejunal interposition may have to be used to replace the hopelessly malfunctioning gastroesophageal segment.

DIVERTICULA

Diverticula are found in the esophagus in about 5 per cent of older patients who are given a swallow of barium. Most of these pouches occur in the mid- and distal esophagus, but they are usually small (1 to 4 cm in diameter) and do not cause symptoms. Extremely rarely an esophageal diverticulum is subject to ulceration or becomes large enough to cause dysphagia. A diverticulum of great clinical importance, however, is Zenker's diverticulum, a pouch which actually arises in the posterior aspect of the hypopharynx but which extends downward between the spine and the esophagus. Patients with this condition—elderly men for the most part—suffer dysphagia because swallowed material tends to fill the diverticular sac, which then compresses the esophagus. Regurgitation of food fouled by stagnation and nocturnal fits of coughing may complicate the picture. Diagnosis

can usually be made by x-ray provided the pharynx is adequately studied as the patient swallows barium. Surgical treatment is necessary to relieve the symptoms of a Zenker's diverticulum but may be complicated by mediastinal infection, disorders of pharyngeal function during swallowing, or recurrence of the diverticulum.

OTHER ESOPHAGEAL DISORDERS

Disorders of Motor Function. In elderly persons normal peristalsis in the lower esophagus above the vestibule may be replaced by so-called "curling" a type of motility which on radiologic study imparts a peculiar beaded appearance to the contracting organ. The condition is usually asymptomatic but may be confused radiologically with esophageal varices. Occasionally the abnormality is sufficiently severe to cause dysphagia and pain on swallowing. The disorder is then known as diffuse spasm of the esophagus or corkscrew esophagus, because the contracting esophagus appears by x-ray to have assumed a bizarre corkscrew pattern. As treatment is relatively unsatisfactory, patients with this disorder may have to subsist on liquid and semisolid food. A longitudinal myotomy of the entire distal esophagus has recently been introduced as a sometimes successful surgical treatment.

The lower esophageal ring is a thin, symmetrical, annular narrowing located 1 to 4 cm above the diaphragmatic hiatus. The ring is caused by a diaphragm-like structure containing strands of connective and muscular tissue. It is covered in some cases by esophageal mucosa on its upper aspect and gastric mucosa on its under aspect. In other cases, the covering epithelium is entirely esophageal. Its etiology is unknown, but the ring is found with increasing frequency in the older age groups and often appears associated with a small sliding hernia. Some 10 to 20 per cent of adults have asymptomatic rings, but if the residual lumen is less than 12 mm in diameter, the ring may cause a highly characteristic syndrome consisting of intermittent attacks of dysphagia, recurring over years, unassociated with any other esophageal abnormality, and precipitated only when the patient swallows meat or other elastic chunks without proper chewing. Treatment usually consists of avoiding such haste. Dilatation is inconstantly successful. In a few, unusually severe cases, surgery with direct cutting or fracture of the responsible diaphragm is indicated as an effective procedure.

In infants with chylasia, the normal tonic contraction of the lower sphincter between swallows is absent and free regurgitation from the stomach occurs. The condition also affects an occasional adult.

About 20 per cent of patients with scleroderma

suffer esophageal involvement with moderate dilatation of the lumen, absent motor function, and variable dysphagia. In doubtful cases the esophageal changes may be the means of diagnosing scleroderma. An almost invariable late complication is a distal esophagitis producing ulceration, stricture, or both just above the gastroesophageal junction.

Perforation and Rupture. Perforation of the esophagus may complicate esophagitis, peptic ulcer, or neoplasm. Rupture may be induced by external trauma or, more commonly, during instrumentation of the esophagus. Sometimes it develops spontaneously in a previously healthy organ. The consequences are a syndrome comprising (1) severe pain, usually substernal, but occasionally epigastric or precordial, and intensified by swallowing; (2) free air in the mediastinum, producing a mediastinal crunch and subcutaneous emphysema palpable within 1 to 12 hr above the collarbones; (3) digestion of mediastinal pleura by pressure and gastric juice with resultant hydro- or hemopneumothorax and respiratory embarrassment; (4) shock; and (5) secondary infection.

Spontaneous rupture is a specific entity that develops suddenly during vomiting or coughing, or occasionally merely after injudicious gluttony. The tear, 1 to 8 cm in length, almost invariably is in the posterolateral portion of the esophagus immediately proximal to the diaphragmatic hiatus. The diagnosis is to be suspected in elderly men (80 per cent of cases) who are suddenly seized by the typical syndrome while vomiting or coughing; it is established by x-ray (air in mediastinum or neck, demonstration of laceration by having the patient swallow radiopaque material, pleuropulmonary abnormalities), thoracentesis revealing gastric contents, and exclusion of myocardial infarction, pancreatitis, and ruptured abdominal viscus. Air under the diaphragm is never found in spontaneous esophageal rupture.

Perforation of the esophagus is highly lethal if not treated vigorously. In early cases, constant esophageal suction and parenteral administration of penicillin (600,000 units) and streptomycin (250 mg) intramuscularly every 6 hr is immediately urgent. If sepsis or signs of increasing mediastinal reaction are not thereby controlled, surgical drainage and repair of the laceration are indicated.

A disorder closely allied to spontaneous esophageal rupture is vertical laceration of the gastroesophageal junction producing, since local vessels are involved, severe and usually exsanguinating hemorrhage. This so-called Mallory-Weiss syndrome usually develops when prolonged vomiting follows an alcoholic bout.

Foreign Bodies. Foreign bodies may cause dysphagia, pain, or perforation of the esophagus. Rigid bodies usually are arrested above the aortic arch,

and elastic material in the distal esophagus. Not infrequently a structural abnormality or disease of the esophagus is responsible for stopping the foreign body.

Varices. Esophageal varices are discussed in Chap. 19, p. 156, and Chap. 280, p. 1686. They do not cause dysphagia or other esophageal symptoms. Radiologically, however, their appearance may be confused with that of cancer or esophagitis.

Plummer-Vinson Syndrome. This syndrome, also known as sideropenic dysphagia, is a cause of dysphagia in women with hypochromic anemia. Often a crescentic web indents the anterior aspect of the cricopharyngeal area; in other cases mucosal atrophy and inflammation appear prominent at the same site. A good diet and iron are usually therapeutic, but sometimes supplemental instrumental dilatation is required. The lesion is regarded as predisposing to pharyngeal carcinoma.

Benign intramural tumors of the esophagus, such as cyst (usually of respiratory tract origin), leiomyoma, fibroma, and neurofibroma, may cause intermittent dysphagia and sharply defined radiologic defects with smooth margins. Some benign tumors, especially adenomas, may produce intraluminal polyps.

The esophagus may be affected by leukoplakia, acanthosis nigricans, sarcoma, Hodgkin's disease, and leukemia.

Intrinsic Disease. Diseases of the aorta, heart, respiratory tract, or mediastinal lymph nodes often displace the esophagus and may appear to narrow the lumen, at least in one diameter. Aneurysms of the aortic arch may compress the esophageal lumen against the spine; otherwise, however, dysphagia is rarely produced by extrinsic esophageal masses. Invasion of the esophagus by bronchogenic carcinoma is possible.

For further discussion of problems considered in this chapter, the reader is referred to Chap. 5, Pain in the Chest, and Chap. 16, Indigestion, Dysphagia, Nausea, and Vomiting.

272 DUODENAL ULCER

Marvin H. Sleisenger

INTRODUCTION TO THE STUDY OF GASTRODUODENAL DISEASE

Serious disease and disorder of the stomach and duodenum, particularly inflammation, ulceration, and malignancy, are extremely common. Although in most instances these processes are not directly related, they give rise to a number of overlapping symptoms and demonstrate characteristic alterations in gastric secretory capacity. Knowledge of pain patterns, of the motor and secretory behavior of the stomach, of the response of the stomach to stress, and of the influences of the neuroendocrine system and of heredity is essential for the proper clinical study of these ailments. Such information provides not only a basis for rational diagnosis and therapy, but a framework on which to build a better understanding of pathogenesis of these diseases, particularly *peptic ulcer* and *gastric cancer*.

Pain. Pain originating in the stomach or duodenum, respectively, is referred to the midepigastrium or subxyphoid. Pain of the second and third portions of the duodenum is low epigastric. Some overlapping, of course, may be encountered. Timing of pain is also important. Distress which is felt while the stomach is empty (except on arising) usually reflects stimuli generated by acid peptic activity; that which appears while eating or immediately thereafter indicates a local disturbance, perhaps inflammation and/or abnormal motor activity, and is often relieved by emesis.

Secretory and Motor Activity. The principal gastric secretions are *hydrochloric acid*, *pepsin*, *intrinsic factor*, and a variety of mucoproteins and

mucopolysaccharides. Clinically, measurement of acid is the most informative and important test. Normally, gastric juice is highly acid, with a pH 1.0 to 1.5; the secretion of the resting stomach averages about 17 mEq of acid in about 500 ml of fluid over 12 hr. The various influences upon acid production—the vagi, eating, stress, neuroendocrine stimuli, etc.—are complex and interrelated (Fig. 272-1); an understanding of their effects is important for intelligent study and management of patients with ulcer disease.

Of all the stimuli of gastric secretion which are sketched in Fig. 272-1, the best established and most important are the *vagus nerves*, the *antral mechanism*, and *histamine*. The production of acid during interdigestive periods, i.e., overnight, in response to sight, smell, or memory of food, and following insulin hypoglycemia, results from vagal activity. Outpouring of acid during meals is due to the release of gastrin by the antrum when food comes in contact with it. Fall in pH below about 1.5 in the antrum leads, in some unknown manner, to a diminution of acid secretion by the fundus. Other factors which depress acid output include contact of the upper duodenum with acid (? mediated by secretin) and the effect of intense fear.

Histamine is the most powerful stimulant of the parietal cell; however, complete understanding of its endogenous activity is lacking. The integrity of the vagi or of the antral mechanism, respectively, is tested when gastric acid is measured in the basal state or after feeding a "test meal" such as gruel or alcohol. Responsiveness of the parietal cell, however, is best tested by histamine injection. The other stimuli shown in Fig. 272-1 will be discussed in later sections of this chapter. Regardless of the relative importance of the roles of these stimuli, measurement of acid secretion is vital to correct clinical diagnosis of the important gastroduodenal diseases.

Methods and Significance of Acid Measurement. Aspiration of gastric juice by nasogastric tube after an overnight fast is the standard method of obtaining samples for determination of acidity. The appearance of a red color upon addition of Topley's reagent indicates the presence of free acid. If no free acid is present, 0.3 to 0.5 mg histamine base is injected subcutaneously and three 15-min collections are obtained. Again, if no free acid is present in any sample and it is imperative to know whether absolute (true) achlorhydria exists, maximal histamine stimulation should be given. A suitable anti-histamine preparation—20 mg chlorpheniramine maleate—is given subcutaneously to minimize side effects, and about 20 min later 0.01 mg histamine per kilogram is also injected subcutaneously. Juice is collected during the 15- to 45-min period after injection of the stimulant and is tested for free acid.

Despite the availability of antihistaminic agents, maximal stimulation should not be given patients with severe allergy, or with pulmonary disease, asthma, hypertension, or significant cardiovascular disease.

Failure to secrete acid after maximal stimulation indicates *absolute (true) achlorhydria*; whereas absence of acid or a lower than normal amount either basally and/or after routine histamine stimulation (0.3 to 0.5 mg) signifies only a *relative hypochlorhydria*. Although values tend to be high for duodenal ulcer, they overlap the normal considerably. Secretion in gastric ulcer has been variously reported as normal or, on the average, slightly below normal. Acid secretion in carcinoma is, on the average, below normal in both the basal and post-stimulation states (Chap. 273). *Absolute achlorhydria*, never encountered in benign peptic ulcer, is common in gastric cancer.

Acid may also be measured, both basally and after stimulation, by means of a "tubeless" method. This procedure consists of administration, following stimulation by caffeine, of resins that exchange a cation, quininium, or azure A for hydrogen. The cation or dye is absorbed and excreted in the urine, where its concentration reflects semiquantitatively the amount of gastric acid which has been exchanged. With the azure A method, 0.6 mg of dye in the urine, determined colorimetrically, signifies the presence of free acid. In a small percentage of instances, when gastric secretion is temporarily diminished, false negatives may be found. If doubt exists, the intubation method should be employed. The cation exchange method is suitable for individuals in whom intubation is unfeasible and for screening large populations for relative hypochlorhydria. A positive test excludes complete (true) achlorhydria. The "tubeless" method, of course, should not be employed in patients with pyloric or esophageal obstruction, malabsorption, severe liver or kidney disease and in those who are vomiting. As with intubation, a negative result is unreliable in patients with gastroenterostomy or pyloroplasty.

The finding of relative hypochlorhydria is of some importance only in ruling out a diagnosis of duodenal ulcer in a patient with suggestive symptoms. Absolute (true) achlorhydria, on the other hand, is an essential point in the diagnosis of pernicious anemia; it also dictates the decision to operate upon patients with gastric ulcer and early or suspicious gastric carcinoma.

Measurement of gastric pepsin is much more difficult and at present has no practical advantage in clinical medicine. In some institutions, urinary pepsin—uropepsin—is measured when pernicious anemia or carcinoma is suspected, but is significant only when absent in more than one specimen. Further, correlation of urinary level with either gastric

FIG. 272-1. Known and possible stimuli of gastric acid secretion. (Based upon an idea of Dr. T. P. Almy.)

acidity or even gastric pepsin secretion is not good, and collection and measurement of 24-hr urine specimens is more troublesome than gastric analysis for acid. Like uropepsin, blood pepsin is usually elevated in duodenal ulcer; it may be high, low, or normal in gastric ulcer; and usually is low in gastric cancer and very low to absent in pernicious anemia. However, as with measurement of gastric acidity, overlap among the categories is so great that a single determination is of limited value. Although study of the mucoproteins of gastric juice has increased greatly, analysis of these constituents has not reached the stage of clinical applicability.

Other Tools of Investigation. ROENTGENOGRAPHIC. In the vast majority of instances, the diagnosis of gastroduodenal disease is confirmed by roentgenographic examination with the barium meal. This must be carried out in all instances of upper abdominal distress, particularly in patients of middle age, those with digestive symptoms lasting longer than a week or two, and those who have bled, grossly or occultly.

DETERMINATION OF BLOOD LOSS. Routinely, determination of hematocrit and test for blood in the stool should be carried out in all patients. Anemia or other evidence of blood loss must be explained, and roentgenographic examination is required.

EXFOLIATIVE CYTOLOGY. The study of exfoliated gastric mucosal cells, obtained in a variety of ways and prepared and stained by the technique of Papanicolaou, has become increasingly accurate in

the diagnosis of gastric cancer. This approach has special applicability in the study of those gastric diseases—polyps and atrophy—which are precursors of cancer.

Endoscopy. Gastroscopy is helpful in establishing the diagnosis of diffuse gastritis, carcinoma, lymphoma, and a variety of benign tumors. It may also aid in the differential diagnosis of benign and malignant ulcer and of upper gastrointestinal bleeding of unknown cause, as well as in evaluation of questionable roentgenographic findings.

Limitations of the procedure are: (1) technical inadequacies resulting from "blind areas" which include a small strip of the posterior wall in contact with the instrument, a small portion of the lower pole of the stomach, the lesser curvature of the antrum, and part of the cardia immediately adjacent to the esophagus; and (2) difficulties in interpretation except by operators who have had vast experience.

Gastric biopsy obtained with an appropriate gastroscopic attachment or by a flexible suction tube inserted into the stomach has contributed further to the differential diagnosis of stomach disease. Biopsy is of value, however, in diagnosis of suspected tumor only if histologic proof is obtained. Biopsy is also extremely helpful in diagnosis of diffuse disease, particularly gastritis and, occasionally, lymphoma.

Response to Stress. The clinician quickly learns that emotional reactions have their effects on the upper gastrointestinal tract. The observations of Wolf and Wolf have led to a better understanding of the effect of stress upon gastric function. Hypersecretion, mucosal hyperemia, and heightened motor activity accompany rage and hostility. In contrast, fear and dejection are associated with hyposecretion and hypomotility. While we cannot conclude that peptic ulcer represents a direct response to emotion, we must recognize emotional influences in its pathogenesis. Stress is also important in the appearance of symptoms which result from delayed gastric emptying and hyposecretion.

Hereditary Influences. Evidence is gradually accumulating of a familial influence in such diseases as duodenal ulcer and gastric carcinoma. Their relationship to "precursor" states such as hypersecretion of gastric acid and pepsin in the former and mucosal atrophy and hyposecretion in the latter is now recognized. The clinician must realize the need for constant surveillance of both the patient with pernicious anemia who may develop a gastric cancer and the young man with a strong family history of duodenal ulcer disease who has recurrent epigastric pain and hypersecretion.

Associated Neuroendocrine Disturbances. Knowledge constantly grows of the number of influences upon gastric secretion and function. In addition

to the role of the vagus and the antrum, the endocrine glands, particularly the adrenals and the parathyroids, and the pancreas appear to affect secretory activity. While the relationship of the central nervous system to the action of these organs is not clear, it is possible that impulses from the hypothalamus via the pituitary may be important. In any event, the clinician who deals with ulcer disease must think about calcium metabolism and be well versed in steroid excretion and pancreatic function (Fig. 272-1).

DUODENAL ULCER

Definition. Duodenal ulcer, the commonest form of peptic ulceration, is an acute and chronic recurrent disorder affecting all ages of the population, but predominantly men from the third to fifth decades. The ulcer is usually circumscribed and located in the first portion of the duodenum and extends to the level of the muscularis. The crater generally has rather sharp edges. About 50 per cent of duodenal ulcers are less than 1 cm in size, the remainder being larger; only about 10 per cent, however, are greater than 3 cm in diameter. Microscopically, the lesion is characterized by coagulation necrosis at the base with infiltration and accumulation of acute and chronic inflammatory cells. Often the ulcer is covered with a thin layer of serofibrinous exudate.

Incidence. The distribution in the population is not exactly known. Estimates of the incidence of the disease, based on necropsy studies, run from 7 to 10 per cent; the ratio of men to women is about 3.4:1. The incidence of this disease varies according to race, and for the sexes within the races, the total incidence of ulcer for Negro men is lower than for whites—again, Chinese have 10 times as many ulcers as Javanese, as noted in a survey from Java.

The only conclusion that can be drawn from a study of geographic and occupational factors in the twentieth century is that the incidence varies from place to place and from time to time in the same place. Over all, the disease does not predominate in any single occupational group—professional, skilled, semiskilled, heavy laboring, or agricultural.

Etiology and Pathophysiology

The cause of duodenal ulcer is unknown. However, much information has been accumulated about gastric secretion in this disease. Whatever the ultimate cause, abnormal elaboration of acid must play a part. Figure 272-1 is a diagram of the various stimuli, established and implicated, which increase acid production. A review of these influences is helpful for a better understanding of this disease.

Secretory Pattern. The outstanding feature of the secretory pattern of the stomach of patients with duodenal ulcer is the basal hypersecretion of acid and pepsin. In addition, all the common stimuli—vagal, food (particularly alcohol, coffee, and beef broth), stress, insulin, and histamine—elicit a greater than normal acid secretion. However, despite the significantly increased mean rate of secretion in patients with duodenal ulcer, in only a minority does the response to the standard secretory tests exceed the upper normal limit. Hence, measurement of secretory rates has only a limited value for identification of duodenal ulcer.

The reason for the increased rate of acid secretion in duodenal ulcer is not altogether clear. Perhaps the most important factor is heightened vagal activity which may explain the high rate of acid secretion during the cephalic and interdigestive phases and its marked reduction after vagotomy. Others consider the dominant cause to be the increased parietal cell mass, since the maximum acid output of the stomach may be quantitatively related to the total number of parietal cells. Whether the number of parietal cells increases before or after ulceration has occurred is not definitely known.

Despite the experimental production of peptic ulcer in animals by continuous stimulation of acid secretion, the hypersecretion of the stomach *per se* in duodenal ulcer may not be the cause of the disease. The persistence of elevated secretion of pepsin and acid after the healing of a duodenal ulcer is evidence that the abnormal secretion is not solely responsible for the disease. Proper understanding of the secretory pattern of these patients is, nevertheless, necessary for intelligent treatment, since the cornerstone of therapy rests upon continuous suppression of acid-peptic activity.

Heredity. A hereditary predisposition seems apparent from the family histories of these patients. Pertinent, perhaps, is the association between the incidence of blood group O and duodenal ulcer. Further, there is a significant coincidence of blood group O and of nonsecretion of ABH substances in duodenal ulcer patients. Since the ability to secrete these substances into the gastrointestinal tract is inherited independently of the ABO groups, the effects of nonsecretion and of the occurrence of blood group O are not only coincidental but also additive. That this association of various genetic factors is causal in duodenal ulceration remains, however, to be proved.

Effect of Stress. Although much has been written of the personality of the patient with duodenal ulcer, no completely acceptable prototype has emerged. We are prone to characterize him as an individual who is hard-driving, conscientious, ambitious, and, in general, successful. Plainly, this is at

once exaggeration and oversimplification. While many duodenal ulcer patients fit this description, it is equally true that a large number are rather shy, soft-spoken, unaggressive, and even withdrawn.

From the time of Beaumont's classical study on the gastric secretion of Alexis St. Martin, increasing attention has been paid to the role of emotional stress in gastric secretion and, in turn, in the genesis of duodenal ulcer. One cannot doubt, on the one hand, an association between anger and hostility and increased acid secretion and, on the other, a frequent temporal relationship between emotional turmoil and the onset of reactivation of duodenal ulcer. Indeed, in this area rather elaborate, but conflicting, theories have been proposed which attempt to relate definite personality patterns and/or environmental influences to the genesis of this disease. These remain, for the most part, unsubstantiated.

Studies in monkeys and man both indicate that behavioral reaction patterns are quite important. However, it is impossible to achieve an acceptable definition of stress which may be universally applicable, and this failure renders difficult the assessment of this factor in an individual case. While stress may lead to hypersecretion of acid, it is important to remember that these patients are capable of hyperresponding in this way to many stimuli of acid secretion.

Neuroendocrine Influences. Some investigators believe that stress affects gastric secretion partly via the anterior hypothalamic and vagal pathway and partly through the posterior hypothalamus—anterior pituitary—adrenal axis. Insulin hypoglycemia can increase secretion of acid in man, as in the monkey, presumably via these pathways. Further, the peaks of secretion which are noted at 1 hr and 3 to 4 hr after insulin are thought ultimately to be due to the action of the vagus and the adrenal glands, respectively. With the available information, however, it is impossible to draw an analogy between effects of hypoglycemia and the stress of daily living.

Adrenal. The virtual absence of duodenal ulcer disease in patients with untreated adrenal insufficiency and the appearance of such ulceration in a number of individuals receiving adrenal corticosteroid therapy has focused a great deal of attention on the possible role of adrenal cortical secretions in the genesis of duodenal ulcer disease. Although patients with adrenal insufficiency secrete less than normal amounts of acid and pepsin, in individuals who develop peptic ulcer while receiving either ACTH or adrenal corticosteroids, acid and pepsin secretion is increased inconsistently. Indeed, in many of these instances there is hypo-secretion or even achlorhydria. Studies of urinary 17-OH-corticoids during periods of activity and

quiescence in patients with duodenal ulcer indicate no variation in the normal function of the adrenal cortex. Indeed, several studies demonstrate that ulcers in rats may be induced by techniques involving stress only in the absence of normal adrenal function.

Parathyroid Glands. Recent studies have demonstrated that incidence of duodenal ulcer is slightly increased in patients with hyperparathyroidism although gastric secretion is normal. Subcutaneous injection of parathyroid hormone—1,000 units—increases volume and pepsin secretion, but not acid, indeed, animal experiments indicate that long-term administration of this hormone depresses secretion, possibly by the inhibiting action of hypercalcemia on the vagus. The mechanism of peptic ulcer formation in hyperparathyroidism, therefore, is unknown.

Hypoparathyroidism is associated with depressed gastric secretion, which, however, is corrected when the serum calcium returns to normal, either by the administration of calcium or parathormone. Thus, the parathyroids seem to influence gastric secretion solely through their effect on serum calcium, since a certain level of serum calcium seems necessary for normal gastric secretion.

Pancreatic Adenomas and Multiple Endocrine Adenomas. The reports of unusually severe recurrent peptic ulceration in the duodenum or jejunum associated with noninsulin secreting islet cell adenomas of the pancreas have aroused a great deal of interest. In addition to the fulminating ulcer diathesis, these individuals secrete excessive quantities of gastric juice, 12-hr collections ranging from 2,000 to 14,000 ml, with a total acid output as great as 10 mEq per hr, about four times the normal mean rate. Ulcerations recur, despite high subtotal gastrectomy and removal of the pancreatic tumor, because this neoplasm often either is malignant with functioning metastases or is scattered diffusely through the pancreas. In almost all instances, total gastrectomy must be carried out in order to prevent recurrent ulceration. Some evidence exists that a gastrinlike substance, produced by the adenoma, is responsible for the gastric hypersecretion which accompanies the severe recurrent ulcerations. Some of these patients may also have diarrhea, steatorrhea, and hypopotassemia.

In approximately one-fifth of these individuals, multiple endocrine adenomas are present involving parathyroid, adrenal, pituitary, and thyroid glands. Since the nonpancreatic adenomas are functioning in only 20 per cent of instances, it is unlikely that the ulcerative process is related in some way to multiple endocrine dysfunction. It is quite difficult to ascribe either the hypersecretory state of the stomach or the severe peptic ulcerations directly to the pancreatic adenomas for two reasons: (1)

significant reduction in gastric secretion following removal of a tumor *alone* has not yet been shown, (2) some patients with duodenal ulcer secrete as much gastric juice and acid as those with ulcer and adenomas.

Relationship of Disorders of Other Tissues to Peptic Ulcer, Liver. The incidence of peptic ulcer is increased in cirrhosis of the liver for reasons which are not clear. Recent observations in patients after portocaval anastomosis for portal hypertension indicate a hepatic role both in control of gastric secretion and in the appearance of peptic ulcer since there is an increase after operation not only in gastric acid output but also in the incidence of peptic ulcer. The increased frequency of ulcer may be related to the former phenomenon, but the reason for the increased acid production is not evident. Perhaps it is due to absorbed histamine which is not detoxified by the liver because of the shunt.

Malignant Carcinoid. Reports indicate that duodenal ulcer is frequently noted in patients with metastatic malignant carcinoid tumor. Increased acid secretion has not been found and, indeed, 5-hydroxytryptamine (Serotonin) which is produced in tremendous amounts by the tumor has been shown to inhibit acid secretion.

Although the incidence of duodenal ulcer is alleged to be increased in *pulmonary emphysema* and *polycythemia vera*, acceptable supporting evidence is lacking.

Clinical Picture

Classical Picture. The symptoms of duodenal ulcer are fairly characteristic and easily recognized. Among them, *pain* predominates, it is usually well localized to an area a few centimeters in diameter, high in the epigastrium or subxyphoid, but sometimes in the midepigastrium or to the right of the midline in this area. The pain is steady, deep, and nonfluctuating and is described as gnawing, but it may be dull, aching, or burning. An outstanding feature of the distress is its *rhythmicity*, since it appears about 1 to 3 hr after meals, when the stomach is empty, it also often awakens the patient from sleep about midnight to 2.00 A.M. However, the pain rarely is noted on arising in the morning. This distress is almost always alleviated by eating. Milk is particularly effective. Nausea and vomiting are uncommon in uncomplicated duodenal ulcer. These symptoms may predominate, however, when ulcer cicatrix has narrowed the pyloroduodenal segment. Occasionally, the pain may radiate into the midback or, indeed, be felt only in this area or in the right flank, indicating possible penetration of a duodenal ulcer (see pp 18 and 1605).

Occurrence of ulceration varies according to season in certain parts of the world, being greater in the spring and autumn in the temperate zones.

This periodicity has been attributed to seasonal changes in atmospheric pressure, dietary habits, incidence of respiratory infection, and stressful situations; however, substantiation is lacking.

The basis for the pain of duodenal ulcer has not been clearly defined. Some observers feel that it is due to the action of acid upon exposed nerve fibers at the edge or base of the ulcer, the pain threshold of which has been lowered by the inflammatory reaction to the erosion. Cited in support of this is the relief from pain which follows ingestion of substances that neutralize acid. Others believe that increased muscular activity initiates pain, stressing the effectiveness of administration of substances (anticholinergics) which greatly reduce smooth muscle spasm. Possibly both mechanisms are interrelated; that is, hydrochloric acid on an inflamed surface leads to direct stimulation of nerve fibers as well as heightened intragastric pressure.

Ulcer of the Pyloric Canal and Postbulbar Ulcer. Variants of the usual clinical picture may be due to location of the ulcer in the *pyloric canal* or *postbulbar segment* (Fig. 272-2). Although patients with the lesion in the pyloric canal often have the same complaints as those with duodenal ulcer, the history may be atypical in 20 to 50 per cent of these individuals. Prominent complaints, not usually encountered with uncomplicated duodenal ulcer, include nausea, vomiting, and other symptoms related to gastric retention. Delay in gastric emptying stems from the spasm and edema of the pyloric canal in which the crater is situated. Because of these symptoms, the patient's appetite may decline and he may lose a considerable amount of weight. In the patient with *postbulbar ulcer*, pain may be felt lower in the epigastrium, be more severe and less responsive to food, milk, and alkali than in a typical duodenal ulcer. Also, ulcer in this location bleeds more readily. Jaundice due to obstruction of the ampulla by edema and spasm is a rare complication.

Duodenal Ulcer of Childhood. The clinical picture of duodenal ulcer in children differs greatly from its counterpart in the adult. In the former group, the location and character of the pain may not be so precise, the child often complaining of diffuse, poorly localized upper abdominal distress, without the rhythmicity of the adult form and often made worse rather than better by eating. Thus, attention may be drawn initially by the child's refusal to eat for fear of discomfort. Bleeding commonly is the presenting complaint. A significant difference between the juvenile and adult forms of the disease is the greater resistance of the child's symptoms to classical therapy, which may be partially due to the difficulty in instituting a dietary regimen; nevertheless, every effort should be made

FIG. 272-2. Postbulbar peptic ulcer in second part of duodenum.

to maintain young patients on a medical regimen (see below). The indications for surgical intervention in this age group are the same as for adults, and, on the whole, results of subtotal gastric resection are good. However, the hazard of resection is somewhat greater in juveniles, since impaired nutrition, which occasionally follows such procedures, may have a very serious effect upon growth and development.

Diagnosis

Physical examination in uncomplicated duodenal ulcer is quite unrevealing, with occasional patients exhibiting variable tenderness in a localized area in the epigastrium. Diagnosis may often be made from the history of the patient; however, confirmation must rest upon radiographic demonstration of the disease. This examination is carried out in most instances using a barium sulfate-water mixture after an overnight fast. The key to the diagnosis is the proper use of compression spot films of the duodenal bulb; one cannot accept inability to demonstrate a filled duodenal bulb with a normal contour or rapid emptying of the bulb as evidence for duodenal ulceration. Conversely, a filled bulb cannot be considered normal unless it has no crater on compression (Fig. 272-3). Even in patients with long-standing disease, a crater may

FIG. 272-3. The importance of compression over the duodenal bulb in demonstration of an ulcer crater. A. Routine film, B, "spot" film with compression.

be demonstrated despite the distortion of the bulb by scars of previous ulcerations (clover-leaf deformity) (Fig. 272-4). Occasionally, however, the distortion of the bulb obscures the crater; in such instances the history of symptoms of an active ulcer may be considered diagnostic. Another radiologic feature of duodenal ulcer may be an abnormal amount of fluid (gastric juice) in the stomach at the outset of the examination, attributable either to hypersecretion or to partial obstruction, provided the patient has fasted overnight.

Occasionally, the measurement of gastric acid in a single random fasting specimen, or in a 1- to 4-hr or overnight collection, may be helpful in supporting a diagnosis of duodenal ulcer in doubtful cases. The average volume and amount of acid secreted by normal individuals is roughly 500 ml and 15 mEq, respectively, over a 12-hr period. In the patients with duodenal ulcer, the average value for acid secretion is about twice normal. Only about 50 per cent of duodenal ulcer patients, however, secrete more acid than the upper limit of normal.

Response to therapy (see below) may also help substantially in the diagnosis of duodenal ulcer. Any individual who gives a history compatible with this disorder and who is relieved of the symptoms in a period of a day or two after institution of therapy for peptic ulcer should be suspected of having this disease. In addition, in some instances of duodenal ulcer disease with gastric retention, intubation of the stomach, with a Levine or Rehfus tube each night or several times daily, with emptying of the gastric contents, may provide dramatic

relief from symptoms. At the same time, this provides valuable information about the secretory state as well as the degree of gastric obstruction.

Differential Diagnosis

The differential diagnosis of duodenal ulcer may be difficult. A great many common disorders are characterized by pain in the epigastrium which may be compatible with, albeit not characteristic of, duodenal ulcer. However, it must be emphasized that, with rare exceptions, the distress of such disorders is *not* relieved by the ingestion of food, milk, or alkali, nor are these disorders apt to become symptomatic when the stomach is empty. The commonest conditions which may be confused with duodenal ulcer disease are referred to as "functional dyspepsia," or "nervous stomach," and chronic gastritis. In these disorders, the patient complains of burning epigastric distress, often of a dull, "heavy" quality which is almost always noted immediately after meals. The symptoms which often make the physician think of duodenal ulcer disease are: heartburn, "sourness," belching, and "gas." While occasionally patients with duodenal ulcer disease complain of heartburn (particularly those who also have an associated reflux of acid gastric juice into the lower esophagus due to hiatus hernia or incompetency of the gastroesophageal sphincter), the other symptoms are relatively rare in duodenal ulcer. These patients are apt to indicate the site of reference with the entire palm of the hand, moving it back and forth and up and down over the entire epigastric area in contrast to the rather

circumscribed area delineated in duodenal ulcer. Moreover, this distress is most often brought on by eating. Often the patients with these disorders will indicate that they feel best "on an empty stomach." The association of stress with the onset or reappearance of symptoms in functional dyspepsia and gastritis is often as striking as in duodenal disease. Most of these patients also note improvement coinciding with relief of tension.

The history of a patient with a *benign gastric ulcer* may be identical with that of one with duodenal ulcer. Frequently, however, patients with gastric ulcer are apt to have distress following meals and may not have as dramatic relief with food (see Chap. 273, Benign Gastric Ulcer). Upper gastrointestinal x-ray examination is, of course, necessary for differential diagnosis.

The distress of *gallbladder colic* differs from that of duodenal ulcer. The former is usually steady and is localized in the midepigastrium or in the right upper quadrant; at times it radiates to the tip of the right scapula; it comes on *after* ingestion of food, particularly a heavy meal, is accompanied by nausea and vomiting, and lasts for hours. Occasionally, the patient has chills or fever and may note dark urine, pruritus, or jaundice if the common duct is obstructed. Such an individual has no desire to eat and almost certainly will obtain no relief from so doing. The pain of *acute cholecystitis* or *common duct obstruction* may be similar to that of posterior penetration of a duodenal ulcer, particularly when the latter involves the pancreas. The pain will be intense, located in the deep epigastrium, often with radiation into the back.

Acute Pancreatitis. When duodenal ulcer is advanced sufficiently to penetrate into the pancreas, the clinical pictures may be identical. Usually the symptomatology of the two disorders differs. Pain of pancreatitis typically is deeper, more constant, and lasts for many hours to days, often with radiation into the back. Some degree of relief is obtained by bending forward or by compression on the abdomen and not by the ingestion of food. Perhaps most important, the onset of pancreatitis is rather dramatic and is often associated with the ingestion of excessive amounts of alcohol and/or food (see below).

Treatment

Peptic ulceration occurs via the action of an acid-peptic juice on susceptible mucosa. Because the factors determining mucosal susceptibility are still poorly understood, treatment is chiefly directed toward reduction of the volume, acidity, and pepsin content of gastric juice. Therapy is further complicated by the fact that in duodenal ulcer the stomach tends to empty more rapidly than normally, thus shortening the effect of the neutralizing

FIG. 272-4. Large duodenal ulcer crater in a 52-year-old woman, demonstrating radiating folds, duodenal deformity, and pseudodiverticulum formation. The crater healed in approximately 3 weeks.

power of ingested food and milk. The therapeutic armamentarium includes diet, a number of antacids, and anticholinergic, tranquilizing, and sedative drugs. To use these to the best effect, singly or in combinations, it is necessary to know in what manner and to what degree a particular agent modifies the composition of gastric juice, as well as the cost in side effects, money, and inconvenience to the patient.

While effective acid neutralization which diminishes peptic activity is possible, there is little at hand to increase the resistance of the tissues to ulceration. It is known, however, that healing is more likely to occur at a satisfactory rate if defects in protein intake are corrected and if certain drugs such as adrenal corticosteroids, salicylates, etc., are forbidden. Physical and mental rest are also important adjuncts to therapy.

Diet. The diet features soft, well-cooked, non-fibrous, nonfried foods with liberal amounts of dairy products. The rationale for such a regimen rests upon its increased neutralizing power and the empirical observation that the patient's symptoms respond more quickly than when normal fare is offered. However, the beneficial effect of food

may be due more to frequency than to content of feedings. Although coarse vegetables, condiments, fried food, and pork products do not stimulate gastric secretion excessively, nevertheless, a great many patients with ulcer will complain of distress after eating these foods as well as after hot or cold liquids. Possibly this effect is related to mechanical, thermal, or chemical irritation of the gastroduodenal mucosa. Feedings should be frequent. Substances such as alcohol, coffee, and beef extracts, which are known to cause not only irritation but marked stimulation of acid production, must be completely eliminated. Because of its effect upon secretion, smoking should be prohibited.

The patient with an active ulcer should be fed frequently from the very onset of treatment. During the initial few days, diet should include hourly milk feedings during the day and every 2 hr throughout the night, as well as semisolids such as puddings, creamed soups, soft-boiled eggs, etc., six times daily. In most cases, broiled and boiled meat, cooked or canned vegetables, and fruit juice may be added. The milk feeding between meals and at bedtime may be given with cheese and crackers. When the patient has been asymptomatic for a few days or so, he may omit hourly milk feedings, but should be maintained on three regular meals and three small, between-meal feedings of milk with crackers or small sandwiches. If weight gain is a problem, or if the patient is obese, or if some predisposition to or evidence of coronary artery disease is recognized, skimmed milk may be used and the amount of starch in the diet reduced.

After there is radiologic evidence of healing, usually in several months or less, the diet may be liberalized to include raw fruit and vegetables, coffee with milk once a day, fried foods, and even small amounts of alcohol before dinner. The diet should be outlined carefully since cooperation is more likely when patients understand the principles of therapy.

Antacids. Antacids reduce peptic digestion of gastric and intestinal mucosa by elevating the pH of the gastric juice. For this purpose, pH levels above 3.5 are desirable, since pepsin shows a maximal activity at pH 1 to 2. To accomplish this aim requires frequent and adequate antacid dosage over periods of weeks or months. The sporadic use of antacids cannot maintain any significant pH elevation and is, therefore, of little therapeutic value.

Calcium carbonate is probably the most effective antacid, and it has no significant effect on acid-base balance. Laxatives may be required to counteract the constipation often associated with its use. With an hourly dose of 2 to 4 Gm, it should be possible to maintain a pH in the vicinity of 4.0, well within desired therapeutic limits. **Aluminum**

hydroxide also tends to cause constipation and has no beneficial effects not exhibited by the use of calcium carbonate. Of occasional clinical importance is the diminished absorption of the tetracycline drugs which are bound by the aluminum ion. It is possible to achieve a pH above 2 to 3 only with a 30 ml per hr dose, alternating on the half hour with 120 ml milk. This program is usually adequate for ulcer healing, even though it does not effect an optimal neutralization of free hydrochloric acid.

Sodium bicarbonate is both rapidly acting and highly effective as an antacid. It has, however, serious limitations because of its ability to produce a marked systemic alkalosis. The alkalosis may be clinically significant and produce a variety of signs and symptoms including anorexia, nausea, vomiting, headache, muscle aches, and tetany. By decreasing the solubility of calcium phosphate, it may lead to the formation of renal calculi and thus seriously affect renal function. The consequence of ingestion of large amounts of both milk and alkali may be a marked rise in blood calcium, and the hypercalcemia may lead to nephrocalcinosis and impairment of renal function. This "milk-alkali" syndrome (p 607) may be treated effectively by discontinuance of the milk and absorbable alkali. Because of its systemic action and the availability of other agents, sodium bicarbonate has little place in the treatment of peptic ulcer.

Antisecretory Compounds. These parasympathetic blocking agents decrease gastric and intestinal motility and the volume, pepsin content, and acidity of the gastric juice. Their effectiveness is frequently limited by the associated side effects, blurring of vision, dry mouth, tachycardia, and in the presence of prostatic hypertrophy, urinary obstruction. In susceptible patients, an attack of acute glaucoma may be precipitated.

It is difficult to obtain clinical evidence sufficient to justify the selection of one anticholinergic drug, natural or synthetic, over another. As a general rule, it may be said of all anticholinergic drugs that the dosage that produces a satisfactory depression in acid secretion also causes one or more of the side effects mentioned above.

Although anticholinergics in effective dosage at bedtime suppress the basal (nocturnal) acid secretion, these drugs do not significantly affect acid secretion in response to feeding or hypoglycemia. During the day, therefore, when given before meals, anticholinergics in themselves are of little use in raising the pH to therapeutic levels. They may, however, delay gastric emptying and prolong the action of simultaneously administered antacids and, therefore, are recommended. The decrease in gastrointestinal motility and spasm may be a factor in relieving the pain of peptic ulceration, although the mechanisms remain unclear. The exact role of

anticholinergic drugs in the therapy of peptic ulcer is still uncertain; comparable results have been obtained in controlled series with placebos. To date there is no evidence that their long-term administration alters recurrence rate, incidence of complications, or the eventual need for surgery.

The action of *sedatives, tranquilizers, and antihistamines* upon gastric secretion is also important. Often the agitated and hyperirritable peptic ulcer patient will benefit from mild sedation in clinically applicable dosage. However, there are no adequately controlled studies which show that tranquilizing drugs promote more rapid healing or prevent complications or recurrences. *Reserpine* in usual oral dosage (approximately 1 mg per day) has no significant effect on the volume and acidity of gastric juice. With 2.0 to 3.0 mg orally, or 1 to 2.5 mg intramuscularly, however, marked increase in both of these parameters may result. Other tranquilizers such as the *phenothiazines* have not been shown to have any effect on gastric secretion other than some diminution in total volume.

Antihistamines have been disappointing, and most studies have shown no significant effect on gastric secretion in man.

Attention to Psychologic Factors. Despite lack of precise psychiatric information about the personality structure and reaction patterns of the patient with duodenal ulcer, the physician must pay attention to these factors. Unquestionably, onset and exacerbation of this disease can often be temporally related to emotional upheavals. While in most instances the physician cannot hope to alter the life situation of his patient appreciably, he can, by close inquiry and attention, seek personality and environment factors which may contribute to anxiety and hostility. Often he is able to give the patient some insight into the nature of his disturbance and, at all times, to afford him sympathy and understanding. Knowledge of the important factors of personality and environment will enable the physician to guide his medical therapy more intelligently with particular reference to prophylaxis, i.e., to institute a more stringent regimen at times when the patient will be under greater emotional strain. Caution must be observed in handling emotional problems, particularly in such matters as encouraging the patient to make dramatic changes in his home or occupational life and in probing deeply into the personal problems which are uncovered. If the need for psychiatric help is apparent, or if the patient expresses a desire for such therapy, appropriate arrangements should then be made.

Use of X-ray Therapy. X-ray therapy of the stomach has been successfully employed in the treatment of duodenal ulcer when response to

medical therapy has been poor. This form of treatment is especially applicable to individuals for whom immediate surgical intervention is not mandatory or to those who are deemed fair to poor risks for surgical intervention. The goal of radiation therapy is temporary destruction of the parietal cells, thus rendering the patient anacidic for periods ranging up to a year. Usually 2,000 to 2,400 roentgen units, total depth dose through anterior and posterior ports, is administered over a course of 15 treatments. It has been found that the ulcers will heal in almost all patients in whom x-ray treatment reduces acid secretion by 50 per cent. Among those whose acid secretion returns in less than a year, the recurrence rate is nevertheless reduced to one-sixth of that in the preradiation period. Hemorrhage and perforation are also reduced by 75 and 50 per cent, respectively. However, secretory levels usually return to normal after a year, and this makes it questionable whether the long-term beneficial results which have been reported are due to x-ray treatment or to close medical supervision.

COMPLICATIONS OF DUODENAL ULCER

The complications of peptic ulcer disease are four in number and broadly constitute the basis for surgical management of this disease. They are: intractability, bleeding, obstruction, and perforation or penetration.

Intractability

The most frequent complication of this disease is intractability. It is characterized by lengthy and frequently recurring periods of moderate to severe activity which render the patient either partially or completely incapacitated. One must be sure of two points before operation is recommended: (1) that the patient indeed has an active ulcer, since some ulcer patients may continuously complain of symptoms, obtain little or no relief from medical therapy, and yet will not have an ulcer crater demonstrable on x-ray examination. In this circumstance the physician must exercise the greatest amount of caution in recommending surgical intervention, since this group of patients contributes the greatest number of individuals with complaints following gastrectomy. (2) One must be sure that the patient has had a fair trial of good medical care, preferably in the hospital, directed by an interested, informed physician. In the initial phase of treatment of an active ulcer, feedings of milk and antacid should be alternated half hourly during the day, and milk (4 to 6 oz) is given every 2 hr at night. In addition to this "around the clock" program, the patient is sedated with phenobarbital and given an antisecretory com-

pound as already outlined. If the patient does not respond to this program in 5 to 7 days, surgery should be carried out.

Bleeding and Massive Hemorrhage

From 15 to 20 per cent of ulcer patients have bleeding as an initial symptom of their disease, and of these, a significant percentage will have this complication as the only evidence of activity throughout the course of their disease. It is most often manifested by the passage of black or tarry stools and on occasion, if the bleeding is very severe, by dark red blood per rectum. Less frequently, the patient will have hematemesis, but this is more characteristic of bleeding from the stomach or esophagus.

Since duodenal ulcer is responsible for at least 60 per cent of upper gastrointestinal bleeding, extra consideration will be given to the problem of massive upper gastrointestinal bleeding. Factors contributing to massive hemorrhage include alcoholism, undue physical or emotional stress, hypertension and arteriosclerosis, excessive salicylate ingestion, infection, fatigue, dietary indiscretion, and prolonged use of the adrenal corticosteroids or phenylbutazone (see below).

In cases of fatal hemorrhage, a branch of the pancreaticoduodenal, gastroduodenal, or gastric coronary artery has usually been involved, in which instance the vessel is often markedly arteriosclerotic and rigid.

Clinical Picture. The signs and symptoms depend upon the degree of blood loss, the rate of bleeding, and the suddenness of onset. Hematemesis is commonly observed in bleeding from gastric ulcer, esophageal varices, and duodenal ulcer, although bleeding from the latter is much more likely to appear as melena (see Chap 18).

Symptoms following massive bleeding usually include faintness, weakness, dizziness, headache, perspiration, thirst, syncope, pallor, and shock (see p 100, Chap. 13). A persistently low blood pressure and a weak, rapid pulse signify a dangerous degree of hemorrhage.

On physical examination, signs should be sought which would indicate less common causes of bleeding. These include telangiectasia of lips, tongue, and buccal mucosa (Weber-Rendu-Osler disease); pigmented spots of the same structures associated with polyposis of the gastrointestinal tract (Puetz-Jeghers syndrome); petechiae, purpura and/or splenomegaly without liver disease, findings which suggest a bleeding diathesis and a blood dyscrasia. Liver disease and possibly esophageal varices are indicated by hepatomegaly, splenomegaly, jaundice, and spider angiomas.

The initial hematocrit value may be normal or elevated in spite of considerable blood loss, since

plasma and red blood cells are lost simultaneously. The magnitude of the hemorrhage may not become evident for at least 12 hr, depending upon the state of hydration and the rapidity with which the total blood volume is restored by hemodilution (see Chap. 18).

Diagnosis. When the diagnosis is uncertain or the source of bleeding has not been established, several procedures should be employed. Among these, gastric intubation, the fluorescein string test, flexible esophagoscopy, and early upper gastrointestinal series have been useful. Initially, a small-bore soft polyethylene nasogastric tube should be introduced into the stomach. If no blood or guaiac positive material can be aspirated, *bleeding has either ceased or originates distal to the pylorus*. In this instance, a string, to the end of which is attached a mercury bag containing a radiopaque monofilament and with similar markers spaced transversely at 1-in. intervals, may be passed through the mouth into the upper small bowel. A flat film of the abdomen is then obtained to identify the position of the string with reference to the esophagogastric junction, body of the stomach, duodenum, etc. Then 20 ml of sodium fluorescein is injected intravenously, and 4 min later the string is withdrawn and examined under ultraviolet light. The site of active bleeding will fluoresce, and its measured distance from the mercury bag will allow identification of the site on the flat film. Should bleeding have ceased, a site may be discovered by the presence of blood or guaiac positive material on a localized segment of the string. Esophageal varices are not a contraindication to either intubation or passage of the string (Fig. 272-5).

Following the "string test" an upper gastrointestinal series should be obtained, provided that the patient is not in shock or bleeding massively. Information obtained beforehand from both intubation and the string test may be of great value to the radiologist. If blood is aspirated from the stomach, indicated diagnostic maneuvers are flexible esophagoscopy and gastroscopy, before barium studies. The former may verify the presence of bleeding varices and may be carried out by a skilled operator before other procedures in cases strongly suspected of having portal hypertension. Before insertion of the instrument, the stomach should be lavaged with cold saline in order to clear the field and perhaps reduce the bleeding. Gastroscopy is most useful when the diagnosis of bleeding from erosions of acute gastritis or from gastric ulcer is suspected. If endoscopy fails to reveal the source of bleeding, and, if the patient's condition is stable, upper gastrointestinal series should be done.

Of major importance is the differential diagnosis of *bleeding esophageal varices*. In the majority of instances the physician will be able quickly to

FIG. 272-5. A 77-year-old white man with gastrointestinal hemorrhage. Upper gastrointestinal series failed to reveal an ulcer crater. Fluorescein string test localized bleeding site to the first part of the duodenum. At operation a deep perforating ulcer in the first part of the duodenum was found. (Courtesy, Dr. Fred Putman.)

ascertain that the patient has liver disease (history of poor nutrition and alcoholism, or of postnecrotic cirrhosis with enlarged or shrunken liver, spider angiomas, jaundice, etc.) and portal hypertension (splenomegaly, abdominal venous pattern). Bleeding may, nevertheless, still be due to ulcer or erosion which occurs in 10 to 15 per cent of cirrhotics. Accordingly, balloon tamponade is best employed when bleeding from varices is established by flexible esophagoscopy. In many instances, however, the patient's condition or unavailability of a skilled operator does not favor use of the procedure. A trial of compression is indicated if the diagnosis of varices had been previously established in an individual who is vomiting blood or if bleeding is massive in a patient with evidence of cirrhosis. When it is employed, the stomach should be aspirated continuously. If blood is returned after several hours of tamponade, bleeding may be presumed to arise from a cause other than esophageal varices, and the apparatus is removed. The measurement of elevated portal pressure by percutaneous splenic puncture supports the decision to undertake a trial of tamponade if esophagoscopy has not been done or is inconclusive (Chap. 18). This procedure should be undertaken only by a

person thoroughly familiar with the technique. Under these circumstances, measurement of the splenic pulp pressure and injection of radiopaque dyes to obtain splenoportograms may provide information that is decisive in the differentiation of bleeding from peptic ulcer or esophageal varices.

Principles of Management of Massive Hemorrhage from Duodenal Ulcer. Treatment of massive bleeding from peptic ulcer includes blood replacement, treatment of shock, acid neutralization, maintenance of nutrition, and reduction of the motor and secretory activity of the stomach. The keystone of therapy, however, is close surveillance of the patient. Since the pulse rate and blood pressure reflect the rate and severity of the bleeding, they should be determined at 30- to 60-min intervals until bleeding has ceased. To ensure a route for possible transfusion of blood, a No. 18 needle should be inserted immediately into a suitable vein and an infusion of glucose and water begun. If the patient is in shock, the foot of the bed should be elevated. Blood transfusions are given until the pulse rate stabilizes at 100 or less, or the blood pressure at 90 to 100 mm Hg, or the hematocrit is maintained at approximately 35 per cent. If there is extreme restlessness or pain, meperidine,

75 to 100 mg may be given. Ordinarily, parenteral sodium phenobarbital, 32.0 to 96.0 mg given every 4 to 6 hr as needed, is sufficient to allay anxiety. Urinary output should be carefully observed, since oliguria or anuria may result from prolonged hypotension. Continuous lavage of the stomach with cold saline solution may help to slow the bleeding.

Since it is technically difficult to perform repeated blood volume determinations during the course of therapy, the total volume of transfusion has to be estimated. Assessment of the blood loss is difficult in view of variability in rate of hemodilution. In general, the patient whose pulse is 100 or over, or whose blood pressure is 100 or less, and who has other evidences of shock has lost at least 1,500 ml of blood; one who has vomited a large amount of coffee-ground material has sustained a loss of at least 1,000 ml (see Chap. 13, Circulatory Failure).

In any event, if pulse and blood pressure do not return toward normal and stabilize, or if hematocrit determinations performed at 4- to 6-hr intervals show no rise or the rise is not maintained after transfusion, it may be concluded that bleeding continues. If this situation obtains after 24 hr of replacement therapy, or if the bleeding has proceeded so briskly within this period of time that 5 units or more of blood (2,500 ml) is required, surgical intervention should be carried out forthwith.

This approach has reduced the mortality from bleeding, particularly in the group of patients over age fifty. The need for rapid blood replacement in the older age group is more urgent since ischemia of the heart, brain, or kidneys may result in fatal myocardial infarction, cerebral vascular accident, or renal failure. Special care must be taken with patients who have heart disease. Packed red cells may be given slowly to such individuals, if shock is not present. When whole blood must be administered, the rate must be adjusted constantly. In this regard, frequent checks of venous pressure should be made via a manometer attached to the transfusion system by a three-way stopcock.

When vital signs have stabilized, whole milk in amounts varying from 90 to 120 cc is administered hourly from 7 A.M. to 10 P.M. and 120 cc at 2-hr intervals throughout the night. An initial period of continuous gastric aspiration may be necessary for 24 to 48 hr, if the patient is persistently nauseated and vomiting, during which parenteral fluids are given. Small feedings of warm skimmed milk are then offered, and these are gradually increased as tolerated.

The hourly regimen is maintained for approximately 24 to 48 hr after active bleeding has ceased. Then the usual routine ulcer management is instituted, consisting of six feedings of a diet from

which fried food, spices, coffee, fresh fruits and vegetables are omitted. Antacids are continued hourly between feedings. At this time, antisecretory drugs such as the quaternary amines (methantheline, propantheline, etc.) or atropine may be given to reduce gastric H⁺, particularly nocturnally. Thus, 15 to 30 mg propantheline may be given before meals and at bedtime. In this regard, use of these drugs is unwise while the patient is actively bleeding, since dosages required to suppress secretion would affect pulse rate, possibly interfere with bladder function, and promote ileus. Since neutralization of acid by frequent feedings appears to be adequate, added benefit from anticholinergic drugs at this stage does not justify their attendant risks.

Sedation is a most important part of therapy. Often the patient is anxious, worried, and restless. It is essential that these symptoms be alleviated and that he be maintained in a calm to drowsy state. The effect of anxiety upon gastric secretion and emptying can be detrimental. Phenobarbital by mouth, 32.0 to 96.0 mg, every 4 to 6 hr will suffice in most instances.

A word of caution about the use of morphine is in order. While it may be of great benefit in allaying anxiety, its use generally in therapy of gastrointestinal tract bleeding is to be condemned, since the drug may seriously depress respiration and blood pressure. Further, it is spasmogenic for smooth muscle of the gut and often causes nausea and vomiting. Barbiturates in adequate doses will effect satisfactory sedation without these undesirable reactions.

Emergency Surgery. Every effort is made to terminate the bleeding by conservative means, yet avoid delay of emergency surgery in those who will not respond to medical management. While the mortality rate with conservative treatment (2 to 5 per cent) is lower than that for surgery performed during active bleeding (8 to 15 per cent), the latter figures, however, are derived from a group of severe bleeders for whom medical therapy had already been ineffectual. Further, the mortality for those individuals over age fifty who continue to bleed after 24 hr of medical therapy exceeds 15 per cent.

The ulcer should be removed surgically, if possible. If this is not feasible, the ulcer bed can be transfixed with sutures or the branches of the gastroduodenal artery leading to the ulcer ligated. Subtotal gastric resection is then performed.

Elective Surgery. Elective surgery is recommended when the patient has suffered one severe or two mild hemorrhages while on satisfactory medical management and is strongly indicated when such an individual fails to follow a medical ulcer regimen. The procedures of choice are then

a standard 75 per cent subtotal gastric resection, hemigastrectomy (50 per cent) with vagotomy, or gastroenterostomy with vagotomy.

Obstruction

Spasm, edema, or cicatrix of a peptic ulcer of the antrum, pylorus, or duodenum may obstruct the stomach. Often a combination of these factors is responsible.

The symptoms of gastric obstruction include progressive fullness after meals, voluntary restriction of food, nausea, and eventually, vomiting of partly undigested food. At first vomiting occurs sporadically, perhaps once in 24 to 36 hr and, characteristically, after the evening meal. As the degree of obstruction increases, vomiting becomes more frequent, despite considerable dilation of the stomach. Distress is almost always relieved by emesis. Occasionally, the patient has typical ulcer pain which is not relieved effectively by food. It must be remembered, however, that prolonged and severe vomiting may occur without organic obstruction.

Diagnosis. The diagnosis is best established by gastric aspiration and roentgenologic examination. Initial aspiration will reveal the degree of obstruction. Not uncommonly, 4 to 5 liters of undigested food may be obtained; however, the volume of aspirate may be small despite complete obstruction if the patient has been constantly vomiting. To ascertain the degree of obstruction in such a situation, the patient should be put on milk feedings, 90 cc every hour from 8 A.M. to 6 P.M., and aspirations may be carried out at 8 A.M. and at 10 P.M. Normally, 100 cc or less of gastric juice is present. If the amount exceeds this, then the difference represents the degree of obstruction. Quantities over 500 cc usually signify cicatricial obstruction. If the nightly retention of gastric juice gradually falls to normal after 3 to 4 days of medical management, spasm or edema is likely. In the presence of cicatricial stenosis, high levels of gastric retention persist. An exception to this formulation is the patient with cicatricial narrowing whose obstruction subsides under therapy. Failure of motility of the antrum, the so-called "antral pump," in the face of organic obstruction is believed to be the cause.

Delay in gastric emptying may be demonstrated on physical examination by a succession splash or by large gastric peristaltic waves moving from the left rib margin toward the right midabdomen. Physical evidences of dehydration include poor skin turgor, dry mucous membranes, and sunken eyes.

The roentgenologic examination gives the most accurate evidence of obstruction and should be made soon after initial decompression of the stom-

ach. The site, nature, and extent of the obstructive lesion may be determined and the degree of retention and stenosis evaluated. Cicatricial stenosis (lumen 3 mm or less) of the duodenal bulb or pyloric canal can be seen on spot films of these segments and is frequently, but not always, accompanied by dilation of the stomach and hyperperistalsis. Other evidences of marked obstruction, in all probability cicatricial, include oliguria with urine of high specific gravity, dehydration, high hematocrit, and a metabolic alkalosis, occasionally aggravated by ingestion of alkali.

Treatment. Patients with prolonged vomiting and dehydration must be given 3 liters or more of normal saline with added potassium, 40 mEq per liter, intravenously, in the first 24 hr, in addition to a volume equal to total gastric aspirate and urinary output. If renal function is normal, alkalosis will thus be readily corrected.

In those patients in whom the pyloroduodenal channel is patent on x-ray, and in whom the stomach is only slightly or moderately dilated, hourly feedings of 120 cc milk may be started, 6 A.M. to 6 P.M. The stomach is then aspirated at 10 P.M., the degree of obstruction ascertained as outlined and, if mild, this program may be continued. Obstruction which is due to edema and/or spasm, associated with pyloric canal or prepyloric ulcer, will subside in 4 to 5 days, however, normal emptying may also be restored in a patient with cicatricial narrowing which will be noted on subsequent gastrointestinal series. If retention of over 150 cc is found after 5 to 7 days, surgery is indicated.

When the obstruction is marked on admission, decompression by continuous gastric aspiration up to 72 hr is advisable. Thereafter, the tube may be clamped, and milk may be either fed or instilled through the tube at the rate of 100 cc hourly for 7-hr periods. Following an additional $\frac{1}{2}$ hr during which the tube is clamped, suction is reinstituted for $\frac{1}{2}$ hr. If the residual for each 7-hr period progressively decreases over 72 hr to 100 cc or less, then the obstruction may be presumed to have been due principally to spasm or edema. If, however, 150 cc or more is aspirated on each occasion, cicatricial stenosis is very likely the cause, and operation is indicated. In this instance, continuous aspiration is reinstituted for 48 hr and definitive surgery carried out.

Each day the volume of the aspirate is replaced by intravenous administration of 5 per cent glucose and 0.9 per cent saline with 20 mEq K⁺ per liter to which soluble vitamin B complex is added. In addition, 500 ml of 5 per cent glucose and water per 24 hr are given for insensible loss. Anticholinergic drugs must not be administered, since they delay gastric emptying. Adequate sedation

must be ensured, as already outlined. Urinary output and blood urea nitrogen must be carefully checked, particularly in those patients with renal disease. Since obstructing ulcers also tend to bleed, stools and hematocrit must be carefully evaluated during treatment.

Subtotal gastric resection is the procedure of choice for cicatricial obstruction, but it should not be performed until the stomach has been adequately decompressed and any acid-base derangement corrected. In some instances a posterior gastroenterostomy is preferable, particularly in elderly patients who are not good surgical risks. This procedure should, if possible, be combined with vagotomy.

Perforation and Penetration

Perforation is the most dramatic complication of duodenal ulcer. It is most frequent in men under the age of forty-five and is rare in women. Typically, the anterior wall is the site of rupture. Although in most instances there is an antecedent history of duodenal ulcer, acute perforation occasionally is the initial manifestation of this disease.

Since rupture of the anterior wall of the duodenum is attended by free release of intestinal contents into the peritoneal cavity, the patient complains of sudden, excruciating epigastric pain, rapidly becomes weak to faint, perspires freely, is nauseated, and often vomits. Because of irritation of the diaphragmatic pleura, pain aggravated by inspiration may be felt over the area of the trapezius ridge.

Physical examination will reveal a pale or gray individual, exhibiting marked diaphoresis, a pronounced preference for remaining still in order to minimize peritoneal irritation, and a normal or elevated pulse rate. The blood pressure is usually normal or only slightly reduced. Examination of the abdomen reveals marked rigidity, particularly in the upper quadrants, and palpation or movement causes the patient to complain of increased pain. If gastric contents have drained into the lower abdomen, there will be tenderness and some guarding in the right lower quadrant or in the flank.

Several hours later the patient may regain normal color, cease to perspire, and be more comfortable, although tenderness and spasm in the upper abdomen persist. This change in the picture signifies only that homeostatic mechanisms have compensated for the initial reaction to stress and in no way signifies that the patient is recovering. The peritoneal irritation will doubtless progress to frank peritonitis attended by fever, tachycardia, and progressive abdominal distention.

Diagnosis is usually made by the characteristic history, together with the findings of a rigid or boardlike abdomen with loss of normal liver dull-

ness to percussion. A flat film of the abdomen taken in a sitting position or lateral decubitus will show free air beneath the diaphragm or lateral abdominal wall, respectively (Fig. 272-6).

Anterior perforation of a duodenal ulcer must be distinguished from several common intraabdominal inflammatory states, particularly acute pancreatitis, acute appendicitis, acute cholecystitis or cholangitis associated with choledocholithiasis, acute intestinal obstruction, mesenteric arterial occlusion, myocardial infarction, ruptured ectopic pregnancy, dissecting aneurysm of the aorta, and inflammatory diseases of the diaphragmatic pleura and lungs.

Of these diagnoses, the one which most simulates perforation is acute pancreatitis. The principal points of differential diagnosis are: pancreatitis typically has a rather gradual onset, the pain often is felt predominantly in the back, is diminished by abdominal compression or bending forward, and lasts for many hours to a day or so. In severe hemorrhagic pancreatitis, however, the onset may be as dramatic and the collapse as complete as in perforation. Indeed, shock is much more likely to occur in the former condition. Abdominal examination reveals tenderness usually over the upper abdomen with some muscle resistance, but nothing approximating boardlike rigidity. Again, there is no obliteration of liver dullness, and an upright film of the abdomen shows no free air. In acute pancreatitis the serum amylase will show elevation, usually over 350 units and, if the patient is seen within a few hours of the onset of the attack, often in the range of 600 to 700 units. While a rise in amylase may attend anterior perforation, due to the escape of pancreatic juice into the peritoneal cavity, it frequently is no higher than 200 to 300 units. Also, a significant rise in serum lipase and some elevation of serum bilirubin and alkaline phosphatase often attend acute pancreatitis.

With *acute appendicitis*, onset of symptoms is insidious, with localization of pain in the right lower quadrant after a period of hours. On examination there is both direct and rebound tenderness in the right lower quadrant as well as rectal tenderness on the right.

In *biliary colic* the pain almost invariably is steady, but rarely may wax and wane, and the episode is more frequently associated with nausea and vomiting. Chills, fever, and jaundice are common. If, however, the acutely inflamed gallbladder perforates, upper abdominal rigidity may be found associated with other evidences of peritoneal irritation which may later become generalized. However, in this instance, a history of acute cholecystitis in the very recent past can be obtained.

The other conditions mentioned in the differen-

tial diagnosis are usually clearly distinguished from acute anterior perforation of a duodenal ulcer by differences in characteristics of pain, location of tenderness or rigidity, and in the case of myocardial infarction, by the abnormalities of the electrocardiogram. With diaphragmatic irritation due to basal pneumonia, the upper abdomen is not usually tender despite rigidity. Of course, confusion will not exist if the patient also has significant cough, sputum, and fever.

Relation of Penetration and Perforation to Intractability. In many instances of "intractability" the basis for the persistence of severe pain which does not respond to usual medical measures is posterior penetration of the ulcer into a neighboring viscus, commonly the pancreas. Often the process culminates in a small perforation which is quickly walled off so that recovery ensues without surgical intervention. When there is penetration into the pancreas, considerable back pain and associated evidences of acute pancreatitis are present.

Continued ulcer distress with localization of pain in the epigastrium and right upper quadrant associated with tenderness may be indicative of a small lateral duodenal perforation which has sealed. In such instances, tenderness, perhaps even with rebound, can be elicited because of the leakage of a small amount of fluid. Usually free air within the peritoneal cavity cannot be demonstrated, and abscess is a rare complication. Once the diagnosis of localized perforation is reasonably suspected, surgical intervention should be undertaken, although in many instances it need not be immediate.

Treatment. If the diagnosis of perforation is established within the first 24 to 36 hr after onset, immediate surgical intervention is indicated. Preoperatively, constant gastric suction, adequate replacement of fluids and electrolytes, broad-spectrum antibiotic therapy (penicillin, 1.2×10^6 units, and streptomycin, 1.0 Gm, daily in divided doses) all should be instituted. In perforations of 36 hr or more duration, conservative therapy may be undertaken. This regimen includes continuous gastric suction, vigorous treatment with broad-spectrum antibiotics, adequate fluid replacement, and administration of blood and albumin as needed.

THE SURGICAL APPROACH TO DUODENAL ULCER

For many years the surgical techniques for the treatment of duodenal ulcer have been constantly revised, based on continuing additions to knowledge of the various roles which parietal cell mass, the vagus, and the antrum play in gastric hypersecretion. It is now generally accepted that no procedure is satisfactory unless it significantly reduces the secretion of hydrochloric acid and pepsin

FIG. 272-8. Upright (sitting) abdominal film of a patient with an anterior perforation of a duodenal ulcer, demonstrating air beneath the diaphragm.

by the stomach. This may be accomplished in a number of different ways. All the procedures to be discussed were developed after the earliest operations of simple gastroenterostomy or "antral exclusion."

Gastroenterostomy and antral exclusion were designed to permit the patient to retain most or all of the stomach; however, the rate of recurrent jejunal peptic ulceration has been prohibitively high (about 35 to 50 per cent) following these procedures. As a result, more radical resections have been done. With bolder resection have come several important inverse relationships. As the amount removed approaches 75 per cent of the organ, the incidence of recurrent ulcer drops; however, as size of the remnant diminishes, the incidence of digestive and nutritional disturbances increases. Reaction to the latter sequence has led many surgeons either to resect less stomach and perform simultaneous vagotomy or to preserve the duodenum, i.e., to do gastroduodenostomy (Billroth I) rather than gastrojejunostomy (Billroth II).

Although a great experience with all varieties of surgical correction has been accumulated, it must be emphasized that the ideal procedure has not yet been developed.

Subtotal Gastric Resection. In this now classic operation for duodenal ulcer, two-thirds to three-

quarters of the distal stomach is removed along with the ulcer in most instances. A loop of jejunum is anastomosed to the resected end of the stomach according to the methods and modifications of Polya or Hofmeister. When performed in this fashion, the incidence of recurrent jejunal ulcer is low, of the order of 3 to 5 per cent at most. Nevertheless, this operation leaves about 15 to 20 per cent of individuals with significant weight loss resulting from serious disorders of digestion, which include anorexia, postprandial fullness, nausea and vomiting, postprandial "dumping" symptoms, and diarrhea.

The "Dumping Syndrome." This syndrome may be described as follows: toward the end of the meal or within a few minutes of its completion, the patient complains of some warmth, a feeling of weakness, often with lightheadedness and palpitations, begins to perspire, feels faint, is apprehensive, and frequently has to lie down. This sequence is most likely to appear after ingestion of carbohydrates which are rapidly hydrolyzed. This disorder is probably related to shift of intravascular fluid into the jejunum in order to dilute hyperosmotic contents; often as much as 20 per cent of plasma volume is thus displaced within a short period of time. The rapid pulse and lightheadedness or syncope are due to hypovolemia; the apprehension,

pallor, and sweating, to sympathetic response. However, a relationship between diminished plasma volume and the symptoms has not been consistently demonstrated. Perhaps the symptoms in some instances are due to autonomic overreaction, based as much upon psychologic factors as upon response to rapid jejunal filling. The management of this distressing condition consists of frequent small feedings which are low in carbohydrate.

The basis for impaired absorption and diarrhea following subtotal gastrectomy has not been established. Factors to be considered include inadequate mixing of food with the digestive ferments from the liver and pancreas due both to bypass of the duodenum and to rapid dispersion over most of the small bowel. In these instances there is significant steatorrhea, with 10 to 20 per cent and occasionally as much as 40 per cent of ingested fat appearing in the stool. Up to 30 per cent of the preoperative body weight may be lost after gastrectomy. Indeed, after high subtotal gastrectomy, a definite malabsorption syndrome may be seen, including symptoms and signs of deficiency of fat-soluble vitamins (paresthesias and tetany due to hypocalcemia, bleeding due to hypoprotrombinemia), vitamin B complex, iron and vitamin B₁₂, etc. (see Chap. 62). Perhaps as a consequence of their poor nutritional status, these individuals have an increased incidence of tuberculosis. Recent evidence indicates that bacterial contamination of the afferent loop is another cause for steatorrhea and malabsorption following Billroth II procedures. Correction may follow a course of broad-spectrum antibiotic therapy such as tetracycline. (Neomycin should not be used, since its administration may be associated with steatorrhea.) Of interest, biopsy specimens of the upper jejunum in patients with steatorrhea following gastrectomy and with gastrojejunostomies reveal atrophic changes of columnar epithelium resembling nontropical sprue. (For discussion of therapy of postgastrectomy problems, see Chap. 274.)

In order to preserve enough stomach to lessen the occurrence of these distressing complications hemigastrectomy with gastroduodenostomy (Billroth I) is now being performed. Several reports indicate that digestive disturbances are fewer and nutrition is better after this procedure, attributable to better reservoir function and mixing of food with duodenal juices. However, the rate of recurrence of ulcer seems to be higher than after standard high subtotal resection and gastrojejunostomy.

A number of investigators feel that maximum protection against both recurrent ulceration and digestive problems can be assured if the distal half of the stomach including the antrum and pylorus is resected and a vagotomy performed. As indicated, there is some evidence that nutrition is better after

FIG 272-7. Recurrent peptic ulcer (marginal ulcer) of jejunum in a patient after subtotal gastrectomy and gastrojejunostomy (Billroth II).

low than after high subtotal gastrectomy. The incidence of diarrhea and dumping syndrome may be less, particularly if gastroduodenostomy is done. Theoretically, then, when the antrum is resected and the vagi are cut, the operation should be satisfactory. However, if vagotomy is complete, there is no evidence that antrectomy will add protection against recurrent jejunal ulceration. If vagotomy is incomplete, one is left with a simple resection of the antrum, an operation known to be inadequate. The rationale of this operation will be established only when it has been shown that the good results reported are not the result of the vagotomy.

Vagotomy alone is unsatisfactory, since it is attended by gastric stasis which stimulates the gastric antrum with release of gastrin, leading to further hypersecretion and reulceration. Therefore, when it is done, a procedure to ensure adequate drainage must accompany it. If the low recurrence rate of ulcer after hemigastrectomy and vagotomy is due principally to the latter, then vagotomy with pyloroplasty or gastroenterostomy will be preferable to vagotomy with resection, since the former combination will ensure retention of a greater amount of reservoir function of the stomach.

Recurrent (Marginal) Ulceration. Following simple gastroenterostomy, and much less commonly after high subtotal gastrectomy or partial gastrectomy with vagotomy, a marginal ulcer may appear on the efferent side of the anastomosis at any time (even up to 30 years), but most often occurs within a year of the procedure (Fig. 272-7). The pain is much like that of duodenal ulcer except that it is located more to the left of the midline in the midepigastrium rather than being high midline or subxyphoid. While it is relieved by eating and by drinking milk or alkali, the response to such measures is less satisfactory than with duodenal ulcer and, in general, the healing of such craters is more difficult.

The diagnosis is often suggested by the history, but frequently there is no pain, and bleeding is the only manifestation. Often these bleeding episodes can be severe, and in many instances the crater will not be demonstrable by x-ray. Whether the marginal ulcer presents with pain or bleeding, intensive management is required. If satisfactory evidence of healing is not obtained, further surgery must be undertaken. If the patient has had only a simple gastroenterostomy, then subtotal gastrectomy with vagotomy is recommended; if the patient has had a subtotal gastrectomy, then vagotomy should be done; if, rarely, the patient has had subtotal gastrectomy and vagotomy, a high subtotal gastrectomy should be performed. In all instances of recurrent ulceration, search for tumor of the pancreas must be made.

273 BENIGN GASTRIC ULCER

Marvin H. Sleisenger

Pathology and Clinical Picture. Benign peptic ulceration of the stomach, like duodenal ulcer, is a chronic, recurrent disease in which there is a localized erosion of the mucosa, extending into the submucosa and averaging 10 to 20 mm in diameter; occasionally, it may be as great as 50 mm (Fig. 273-1). The ulcer usually is single, but occasionally dual or multiple. In most instances the edges of the ulcer crater are sharply defined, with a surrounding area of inflammatory edema, hyperemia, and infiltration. The base of the ulcer is generally covered with a small amount of fibrinous or fibropurulent exudate which overlies zones of necrosis, granulation, and fibrosis, depending upon the degree of healing which has occurred. In the more chronic penetrating variety, the muscle coats may be interrupted and interspersed with fibrosis; in these instances, blood vessels may become thrombosed or eroded.

The clinical picture is variable. Epigastric pain is the prominent presenting symptom. As in duodenal ulcer, it is gnawing or aching, varies from mild discomfort to severe distress, appears one to several hours after meals, lasts 30 min or more with prompt relief upon ingestion of food or alkali. Distress at night seems to be rare. Frequently,

FIG. 273-1. Large chronic gastric ulcer 4.1×2.5 cm in diameter and 8 mm in depth on the posterior wall of the stomach, lower third, producing a massive fatal hemorrhage. A second smaller ulcer is seen on the left.

however, the story is different. The discomfort may be burning or cramplike, may not be relieved by food or alkali, and in fact may be aggravated by eating. Also, the area of the distress is apt to be more diffuse than for duodenal ulcer, covering the major part of the epigastric area and often extending over the left lower anterior rib cage. Periodicity of gastric ulcer activity is not nearly so striking as that of duodenal ulcer, in which recurrences are most common in the spring and autumn.

As with duodenal ulcer, radiation of the pain to the back is not uncommon and suggests penetration of the lesion beyond the serosa into adjacent organs, particularly the pancreas.

The exact clinical incidence of gastric ulcer is unknown, but it is thought to be about one-tenth as common as duodenal ulcer. Accurate determination is difficult, since small and/or rapidly healing ulcerations are extremely difficult to demonstrate. As with duodenal ulcer, this disorder occurs more commonly in men than in women, the ratio in most large series varying from 2:1 to 4:1.

The majority of gastric ulcers occur at two sites: the prepyloric area and along the lesser curvature. About 90 per cent of lesser curvature ulcers are located in mucosa containing pyloric glands, suggesting that the latter is less resistant than mucosa with acid and pepsin secreting cells. Less common sites include the posterior wall of the body of the stomach, along the greater curvature, and the area of the cardia and cardioesophageal junc-

tion. A gastric ulcer may occasionally appear in association with either an active or a healed duodenal ulcer.

Etiology and Pathogenesis. In benign gastric ulcer, unlike duodenal ulcer, gastric secretion rarely is above normal. Aside from the digestive action of acid peptic juice upon the mucosa and its underlying layers, little is known of the etiology and pathogenesis of gastric ulceration. Nevertheless, certain facts are available which suggest that this disease is different from duodenal ulcer. The incidence appears to be higher in patients with chronic pulmonary disease and rheumatoid arthritis and in those treated with certain drugs, particularly adrenal steroids (see below). Since the secretion of acid is often normal or, as found in other studies, slightly depressed, ulceration may be due to some defect either in the protective mucus of gastric juice or in tissue resistance, or both. Since a normal regenerative capacity is important for adequate resistance, it is possible that impaired protein metabolism may play a role in the genesis of gastric ulcer. The importance of mucosal regeneration in relation to mucosal integrity is suggested by the frequency of atrophic changes adjacent to the ulcer area of the stomach, perhaps resulting from an antecedent gastritis.

The increased incidence of gastric ulcers in patients with gastric retention due to pyloric obstruction or following vagotomy alone or combined with high lying gastroenterostomy has stimulated interest in the role of the antrum in the genesis of gastric ulcer. Evidence obtained from experiments with dogs indicates that antral stimulation by contact with food or by distention results in hypersecretion of acid mediated by gastrin (Chap. 272). In addition, reflux of alkaline fluid into the antrum after gastroenterostomy abolishes the normal antral inhibition of gastrin release, thereby promoting acid secretion. A clinical observation which supports the importance of the antrum is the healing of proximal gastric ulcers after simple antrectomy. Although psychologic factors may play a significant role in the genesis of gastric ulcer, helpful studies of the personality patterns of patients with gastric ulcer or of the role of emotional trauma are not available.

Acute Gastric Ulcer. Gastric ulceration may develop acutely. A major difference between the acute ulcer and the more common variety is the lack of fibrosis and of endarteritic vascular thrombosis in the former which renders these craters more liable to perforation and bleeding. Indeed, one of these complications may be the presenting symptom in many instances. Acute gastric ulcer is likely to occur in the situations discussed below.

Drug-induced Gastric Ulcer. A large number of drugs, particularly the adrenal steroids, may induce

FIG. 273-2. Large gastric ulcer of the antrum in a 56-year-old woman with rheumatoid arthritis treated with adrenal corticosteroids for 6 years. This is a common location and appearance for "steroid ulcers." (From W. H. Kammerer, R. H. Freiberg, and A. Rivelli: *Arthritis and Rheumatism*, 1:122, 1958. Reprinted with permission of the author and publisher.)

gastric ulceration (Fig. 273-2). The incidence of peptic ulcer in patients receiving adrenal steroids varies from 7 to 32 per cent, depending upon the length of administration, the dosage employed, and the nature of the underlying disease being treated with the steroids. The highest incidence is recorded when patients receiving steroids are subjected to routine roentgenographic examination, thus revealing asymptomatic ulcers. Steroid ulcer seems to occur more frequently in patients with rheumatoid arthritis, lupus erythematosus, and certain skin diseases, and less frequently in those with ulcerative colitis and malignant diseases. Whether duodenal or gastric in location, these ulcers may be asymptomatic, may often bleed severely, and occasionally perforate without prior symptoms. Although they are not generally associated with elevated secretion of acid and pepsin, nevertheless, they frequently heal on a regimen of a high protein diet and frequent feedings, with antacids and anti-secretory drugs (see below).

The appearance of benign gastric ulcer of the stomach, frequently severe enough to bleed or perforate, may be associated with the administration of certain other therapeutic agents. Drugs which block adrenergic activity, such as *tolazoline hydrochloride* (Priscoline), *hydralazine* (Apreso-

line), and *hexamethonium*, are thought to induce ulceration by augmenting gastric acid secretion via a relatively greater vagal influence. Two other agents, *phenylbutazone* (Butazolidine) and *reserpine*, stimulate acid production, the former by direct action on the parietal cells, and the latter by central suppression of sympathetic stimuli. In this regard, the usual therapeutic dose of reserpine, 1.0 mg daily, does not increase acid secretion, but 2.0 mg or more may elevate both the volume of secretion and the total acid. To some extent these drugs probably act by local irritation. It is likely that *cincophen* and *salicylates* also cause acute inflammation and erosion by their irritative action, although salicylates may also increase secretion. The ulcerogenic effect of *caffeine* probably arises as a result of increased acid secretion and local mucosal irritation. It is also possible that the ulcerogenic potential of some or all of these agents results partly from an adverse effect upon the blood flow to the mucosa.

The role of *salicylate* ingestion in upper gastrointestinal bleeding has received considerable attention of late. Data which suggest that salicylates cause upper gastrointestinal bleeding, particularly in patients with preexisting peptic ulcer disease, are sufficiently impressive to restrict the use of

these agents, as much as possible, in such individuals and in those without known ulcer disease who have bled following their use. The quantity of salicylate required to induce bleeding in susceptible individuals varies, but may be as little as 0.6 Gm three to four times daily for several days. Chronic occult bleeding has also been observed. The "buffering" of aspirin with alkali does not prevent this type of bleeding. Perhaps administration of salicylates in either dispersed or enteric-coated forms may reduce the incidence of this effect; however, evidence at present is inconclusive on this point.

Ulcer Associated with Stress. Peptic ulceration may occur during acutely or chronically stressful situations. In many instances these ulcers are associated with cerebral vascular lesions, particularly subarachnoid and intracerebral hemorrhage and thrombosis. Documentation of stress ulcers may be difficult; indeed, suspicion of their presence may be aroused only by a severe or exsanguinating hemorrhage. Such ulcerations are also associated with burns, multiple injuries, fulminating sepsis, snake bite, exposure, and many other stressful situations.

Diagnosis of Gastric Ulcer. Although variable, the history in gastric ulcer may be highly suggestive; the physical examination, except possibly for some tenderness in the epigastrium, is usually unrevealing. Generally, also, there is no anemia and the stools are often negative for occult blood. The diagnosis of gastric ulcer can be established with certainty only by radiologic examination, gastroscopy, or surgical exploration.

Radiographically, the benign gastric ulcer of the stomach appears as a discrete punched-out crater which, if located on the curvature, extends beyond its margin. Characteristically, radiating mucosal folds extend to the crater. Benign gastric ulcers are smooth or only slightly irregular; a rim or "halo" of radiolucency, due to inflammatory edema of the margins of the crater, separates the crater from the remainder of the barium-filled stomach (Fig. 273-3).

Differentiation of Benign and Malignant Gastric Ulcer. The clinical history does not usually distinguish the benign from malignant ulcer. It is generally thought that carcinoma of the stomach is rare in the third and fourth decades; however, enough exceptions have been encountered to make the age factor unreliable in differential diagnosis. A long history of recurrent symptoms is more characteristic of benign gastric ulcer, but certainly this disease process may be acute in onset and brief in course. Loss of appetite and significant loss of weight are more characteristic of malignancy, but these symptoms are not specific for it. The pain may be identical in both conditions if peptic ulcer-

ation occurs within the malignancy. In this situation, relief with milk or alkali may not distinguish between the two conditions. Frequently, pain in malignant gastric ulcer is due to neoplastic involvement of dorsal root nerve fibers; in this instance food and antacids are, of course, ineffective in relieving it. Anemia or occult blood in the stool suggests a malignant process.

The vast majority of gastric ulcers are benign. In order to differentiate the ulcer from ulcerated malignancy, five diagnostic criteria should be routinely employed. These are: determination of capacity for acid secretion, careful study of the upper gastrointestinal x-ray, cytologic study of exfoliated cells, gastroscopy and biopsy, and response to therapy as measured roentgenographically.

The x-ray appearance of the lesion is one of the most important aids in differentiating benign from malignant gastric ulcer. Presence or absence of a tumor mass at the margins of the ulcer crater or evidence that the ulcer is in the midst of a tumor is crucial in this matter. Some of the features of benign gastric ulcer which have already been alluded to, such as presence of radiating folds and extension beyond the contour of the curvature, may be present in a malignant ulcer. Conversely, the large translucent shadow between the barium-filled crater and the stomach, reflecting edema of benign gastric ulcer, may be confused with a corresponding one in carcinoma. This latter crescentic shadow between the gastric wall and lumen is due to tumor infiltration about an ulcer which does not project beyond the contour of the curvature (Carmen's meniscus sign) (Fig. 273-4). Although it has long been alleged that ulcers of the greater curvature and the prepyloric area are more likely to be malignant, careful analysis of such craters in these areas does not support the contention. Therefore, diagnosis must not be made on the basis of location.

While both conditions may be associated with a relative hypochlorhydria, the likelihood of malignancy is increased if the patient has complete (true) achlorhydria, for such a secretory response is very rare in benign gastric ulcer. Indeed, this finding necessitates surgical exploration. The converse, i.e., that the capacity to secrete free acid indicates a benign process, does not hold and, *per se*, should never be a criterion for excluding malignancy.

Several additional aids in laboratory diagnosis are very helpful. One of these has been the study of exfoliated cells from the gastric mucosa, prepared according to the method of Papanicolaou. Techniques for obtaining such cells include lavage with saline or chymotrypsin or mucosal abrasion with a brush or balloon covered by a net. Accuracy of cytologic diagnosis of carcinoma varies from 60 to

A

FIG. 273-3. A. Large benign gastric ulcer on the lesser curvature of the stomach of a 42-year-old woman. Note the projection of the crater beyond the contour of the curvature and the prominent area of radiolucency which separates the crater from the stomach lumen. (Compare with Fig. 273-4.) B. After 3 weeks of therapy the ulcer has healed.

60 per cent. When combined with radiology, the percentage of positive diagnosis of carcinoma approaches 90 per cent (Table 273-1). If the results of either of these procedures indicate malignancy, operation should be performed without delay.

Gastroscopy with or without biopsy may contribute to correct diagnosis. Gastroscopic differentiation of the lesion alone is not completely reliable. Differentiation of benign from malignant gastric ulcer must not rest on gastroscopic features alone, since often even at operation the surgeon is unable to tell whether or not the lesion is malignant. Also, "blind areas" in the cardia and antrum escape the view of the endoscopist. Biopsy is decisive only when positive.

Finally, the behavior of the lesion during intensive medical therapy, preferably in the hospital, is a most important criterion in the differential diagnosis. While it is alleged that malignant gastric ulcer may heal completely during a trial of medical therapy, such an event is rare. The incidence of complete healing of malignant ulcer is probably no greater than 1 per cent. Most benign ulcers either heal completely or nearly completely in a period of 4 to 6 weeks. Failure to respond in this manner must be considered presumptive evidence of malignancy (Fig. 273-5). Nonetheless, one must remember that ulcers in older individuals, as well as in individuals with moderate to severe nutri-

FIG. 273-4. An ulcerated carcinoma in a 46-year-old man, demonstrating both crescentic crater within the contour of the lesser curvature and the area of radiolucency between the gastric wall and lumen. (Carmen's sign.) (Compare with Fig. 273-3.)

tional problems, may heal more slowly. Conversely, it is astonishing how rapidly large ulcers may disappear (Fig. 273-3).

If one uses all these criteria, including the trial of therapy, the incidence of erroneous diagnosis in malignant gastric ulcer will be less than 5 per cent and, in institutions where great experience has accumulated, will probably be about 2 or 3 per cent. This is a wholly acceptable approach, since the delay of 3 to 4 weeks in operating has not been satisfactorily demonstrated to affect the prognosis of malignant ulcer. Indeed, several studies of patients with gastric ulcer have shown that operative mortality in benign ulcers, suspected preoperatively of being malignant, was higher than that from cancer which had been misdiagnosed as benign ulceration.

The surgical approach to uncomplicated, non-recurrent gastric ulcer should not be based upon the possibility of malignancy in the face of criteria which indicate that the process is benign, rather, it should be based primarily upon either unequivocal or strongly suggestive evidence of cancer derived from careful studies and observation. Conservative medical treatment demands that the patient be kept under close surveillance and that decision regarding surgery be made promptly after

the trial period. However, since the prognosis for small gastric carcinoma which has ulcerated is vastly better than that for gastric cancer in general (5-year cure rates of 25 per cent versus 5 to 10 per cent), the physician should decide in favor of surgical intervention in unresolved or doubtful cases. The rare occurrence of marginal ulceration after subtotal gastrectomy for gastric ulcer as well as the lower incidence of dumping syndrome and other nutritional problems further support this attitude.

The possible relationship between benign gastric ulcer and the subsequent development of stomach cancer is pertinent to this discussion. In five reported studies, 0.4 to 3.0 per cent of patients with benign gastric ulcer developed carcinoma of the stomach within 10 years. The average was 1.5 per cent. These figures per se do not warrant gastrectomy for benign ulcer as a cancer prophylaxis. In many instances the carcinoma is located at a site different from the antecedent ulcer, which had long since completely healed, making it difficult to accept a cause-effect relationship.

Treatment. The management of the patient with benign peptic ulcer of the stomach follows the same general principles outlined for duodenal ulcer. The major difference is that, if possible, the patient should be hospitalized during the period of treatment to afford maximum opportunity for the ulcer to heal. Obviously, this is of great importance, since the extent of healing will determine whether operation will be performed. Removal of the patient from his environment will provide mental as well as physical rest and will promote the strong doctor-patient relationship so important to good management.

Naturally, all drugs which might contribute to the ulcerative process such as adrenal steroids, salicylates, Butazolidine, etc., should be discontinued as rapidly as possible. Occasionally, however, adrenal steroid therapy will have to be maintained or reduced very slowly. The ulcers will often heal even with continued steroid administration.

Although secretion of acid and pepsin may be subnormal in the patient with benign gastric ulcer, healing is slow when nutrition is poor and nitrogen balance is negative, as is commonly the case in chronic pulmonary or rheumatic diseases or with adrenal steroid therapy. Accordingly, diet should consist of frequent feedings of foods with high protein content as well as substantial buffering power. At onset of therapy, 4 to 8 oz milk is given hourly. After a few days, three regular meals and a bedtime feeding may be added. Several times daily milk feedings may be supplemented with protein hydrolysates. (For further details of diet, see Chap. 272.)

Antacid and antisecretory drugs are also benefi-

FIG. 273-5. Large lesser curvature ulcer in a 42-year-old man which appeared benign (A) but which showed incomplete healing in 5 weeks (B). At operation an ulcerated carcinoma with metastases was found.

cial. Since relief from anxiety is essential to optimum healing, sedatives should be given in the same manner as for duodenal ulcer. (For details of use of all these drugs as well as tranquilizers, antacids, and antisecretory compounds, refer to Chap. 272.)

Indications for Surgery. The most compelling indication for surgery in gastric ulcer is the suspicion of malignancy which arises from the demonstration of either histamine fast achlorhydria, exfoliated malignant cells, evidence of tumor by x-ray, or failure of the ulcer to heal in a 4- to 6-week period of optimum therapy (Fig. 273-5). Other common indications for surgical intervention include recurrence, bleeding, and perforation. Special mention must be made of these conditions.

Bleeding gastric ulcer carries a graver risk than its duodenal counterpart. Indeed, the single greatest cause of mortality from upper gastrointestinal bleeding, aside from esophageal varices, is gastric ulcer. This is particularly true in the age group over fifty, especially in the presence of hypertension or other cardiovascular disease. Should bleeding persist despite transfusion and supportive measures, early operation is advisable (see the section on upper gastrointestinal bleeding in Chap. 272, Duodenal Ulcer).

Recurrence of benign gastric ulcer has been estimated to be as high as 25 to 55 per cent. Since the disease is disabling and increasingly hazardous as the patient grows older, surgical intervention is recommended for recurrence.

Free perforation of a benign gastric ulcer is unusual, but *penetration* into the pancreas is not. The signs and symptoms of these complications are similar to those which are outlined in the chapter on duodenal ulcer. Surgery is also indicated in these instances.

Indications for X-ray Therapy. When strong contraindications to surgery exist in elderly and/or chronically ill individuals with gastric ulcer, radiation of the stomach, which diminishes gastric secretion by its effect upon secretory cells and also induces a vascular fibrosis, may be employed. Recurrence rate, though reduced, is still high (40 per cent). (For details of treatment and its effect upon secretion, see Chap. 272.)

Long-term Management. In the long-term medical management of the patient with a healed benign gastric ulcer, the following program is usually employed. The patient should be seen routinely at regular 3- to 4-month intervals. An upper gastrointestinal tract series should be done routinely once each year and at any other time that symptoms reappear, to determine whether or not recurrence has taken place. While the patient need not be on a "strict" dietary regimen, he should avoid black coffee, alcohol, fried and spicy foods and should be encouraged to continue to eat between meals, usually a milk feeding with crackers and cheese. At appropriate times of stress, the physician should employ sedatives and tranquilizers and antisecretory (anticholinergic) drugs, as already outlined in Chap. 272. Certain drugs (adrenal steroids, sali-

3 to 7 Gm after meals and appropriate doses of vitamins A, D, and K. In some instances, intermittent 2-week courses of tetracycline, 1.0 Gm daily by mouth, may reduce steatorrhea in patients with afferent loop stasis associated with gastroduodenostomy or esophagojejunostomy. Anticholinergic drugs may also reduce diarrhea. Interposing a loop of jejunum between the esophagus and duodenum after total gastrectomy creates a "reservoir" and reduces the incidence of disturbing postprandial symptoms, nutritional problems, and regurgitant esophagitis, which are noted after the standard Roux-en-Y esophagojejunostomy.

GASTRITIS

Gastritis is an inflammation of the mucosa of the stomach with or without hypertrophy or atrophy and may be associated with distressing symptoms of indigestion. Clinically, it may be conveniently divided into the acute and chronic forms.

Acute Gastritis. Although the epithelium of the gastric mucosa is capable of rapid regeneration, noxious stimuli may cause diffuse hyperemia, edema, exudation, and if sufficiently severe, erosion and bleeding. Rarely, the erosive process may penetrate the muscularis mucosa to become an ulcer. Although regeneration takes place, some glandular elements may disappear and the submucosa may become scarred. Contributory factors include malnutrition, infection (virus, staphylococcus, salmonella), ethyl alcohol, many drugs (aspirin, Butazolidin, etc.), and a wide variety of chemicals (caustic soda, phenol, acids, etc.)

Symptoms. Anorexia, nausea, diffuse epigastric discomfort ("heaviness" and "burning") are the cardinal symptoms; occasionally, vomiting and profuse bleeding complicate the picture. In the event of bleeding, the clinical picture depends largely upon the amount and rapidity of blood loss and may vary, therefore, from slight pallor to marked diaphoresis and shock. (In this regard, diffuse acute gastritis per se is not so common a cause of bleeding as acute erosion or ulcer without diffuse inflammation.) If vomiting is severe, sufficiently prolonged, or untreated, the patient may rapidly become weak and dehydrated, and he may suffer shock. The abdomen is usually flat, but in those who are very ill, it may be distended.

Diagnosis may be confirmed only by gastroscopy. The mucosa usually heals completely in 3 to 4 days, however, repeated episodes may lead to permanent damage.

Treatment. Management of gastritis depends upon the cause. Withdrawal of the offending agent is necessary. If the patient is seen early, the stomach should be lavaged with saline. Fluids, electrolytes (Na⁺, K⁺ particularly), and blood are given

as indicated. Staphylococcal food poisoning and salmonellosis may be treated with broad-spectrum antibiotics in severe cases; however, supportive measures are usually sufficient.

Chronic Gastritis. In chronic gastritis, the recurrence of inflammation is often superficial and affects the surface of the mucosa without causing atrophy of the glands. The mucosa is of normal depth, and although the inflammatory changes may be slight, moderate, or severe, the lesion is capable of complete resolution. However, irreversible changes may occur which progress to atrophic gastritis. Atrophic gastritis is characterized by a more diffuse inflammation of the mucosa combined with varying degrees of atrophy of mucosal elements. Complete resolution is not likely, and the condition frequently progresses to complete mucosal atrophy. It must be emphasized, however, that the degree and extent of inflammation and atrophy often overlap.

The typical clinical picture of chronic gastritis is that of a middle-aged patient with a history of indigestion extending over several years. Symptoms are usually intermittent and consist of distress in the epigastrium occurring almost always immediately after meals, particularly if the patient has partaken of a great deal of fried or spicy food, often with alcoholic beverages, or if he has over-eaten. Nausea and vomiting may be a feature.

Bleeding occasionally occurs in chronic gastritis, but is rarely of sufficient magnitude to warrant emergency surgical intervention. It seems to be associated in most instances with "spree" drinking of alcohol.

Physical examination of these patients is unrevealing. A small number may have diffuse epigastric tenderness. Rarely, there will be some evidences of anemia or of vitamin deficiency.

Laboratory investigation of these complaints reveals varying secretory patterns which depend mainly upon the degree of atrophy of the gastric mucosa and its parietal cells. About 25 per cent of patients with superficial gastritis will have a normal response to histamine, whereas an equal number will show hyposecretion, and about 45 per cent will not respond at all. As atrophy progresses, the incidence of histamine fast achlorhydria arises steeply, with only about 5 per cent of these individuals capable of secreting any acid after such maximum stimulation. Radiologically, no abnormalities may be detected and gastric emptying is normal.

Relationship to Peptic Ulcer and Carcinoma. Studies on the relationship between chronic gastritis and peptic ulcer indicate that this entity is more closely related to gastric than duodenal ulcer. Gastritis initially may be patchy and limited, and the involved area may be digested by acid-peptic juice. The zone which ulcerates and its surround-

ing mucosa are incapable of normal secretion, which perhaps explains the reduced acidity in a large number of patients with benign gastric ulcer. Several studies of gastric mucosa in duodenal ulcer revealed that gastritis is associated in only a minority of instances.

The role of chronic gastritis is also pertinent in the genesis of carcinoma of the stomach. An old theory holds that gastric carcinoma has its origins superimposed upon inflammatory changes, since pathologists have reported that carcinoma is frequently associated with such changes. Yet, limited studies of patients with chronic gastritis have revealed no definite relationship to gastric carcinoma, and none of the patients in several series has developed the latter disease. However, it is noteworthy that as chronic gastritis progresses the same secretory pattern characteristic of gastric carcinoma, that is, hyposecretion or achlorhydria, develops.

The anemia of chronic gastritis is usually of the iron-deficiency type, and several factors probably contribute to this; anorexia leads to a diminished food intake, which is often low in iron and protein; in a minority of instances, iron absorption may be impaired; the anemia may result from repeated small hemorrhages. In some instances atrophy may be complete, resulting in failure of absorption of vitamin B₁₂ and in pernicious anemia.

Treatment. The treatment for chronic gastritis consists of encouragement of a satisfactory caloric intake and of a relaxed atmosphere at mealtime, abstinence from foods which are prone to cause difficulty, such as fried food and alcohol, and the administration of nonabsorbable antacids, which are somehow effective in the face of hypochlorhydria or even achlorhydria. Little basis exists for the belief that dilute hydrochloric acid with meals is beneficial. If the blood smear, red blood cell indices, and if necessary, serum iron and iron binding capacity reveal an iron-deficiency anemia, ferrous salts should be given by mouth. Often, however, response is poor despite apparently normal absorption and the absence of occult blood loss. If complete gastric atrophy and achlorhydria are present, the anemia may be megaloblastic, in which instance parenteral vitamin B₁₂ should be administered. One of the most important aspects of therapy is to reassure the patient and to explain the nature of the symptoms and their relationship both to inflammation of the mucosa of the stomach and to stressful situations. It should be emphasized that there is no known relationship to future development of cancer. Often such reassurance brings dramatic relief.

Diffuse Giant Hypertrophic Gastritis. Another variety of "gastritis" may be associated with the same symptoms found in chronic superficial or

atrophic gastritis. This entity is called "diffuse giant hypertrophic gastritis" and was first described by Menetrier in 1888. It is a rare disease of the stomach characterized by the presence of very prominent folds with profuse epithelial proliferation and some inflammatory reaction. The lesion may diffusely involve the whole gastric mucosa, or it may be localized in distribution, particularly in the antrum. The folds may be swollen and tortuous so as to appear polypoid and may be as great as 3.5 cm in diameter. The mucosa is soft and pliable, but may become relatively fixed if inflammation is great. Histologically, changes consist of hyperplasia of the surface epithelium and infiltration of the interstitium by inflammatory cells.

This disease or condition appears principally in men from the fourth to the sixth decade who complain of the same postprandial epigastric pain and distress as do most patients with chronic gastritis. In addition, they may also note vomiting, weight loss, and bleeding.

The disease may be strongly suspected from the radiologic appearance of the stomach, which is characterized by very large, tortuous, often polypoid, folds in one or more areas of the stomach (Fig. 274-5). Since carcinoma, granulomas, and lymphosarcoma may be indistinguishable on roentgenogram, further studies are strongly indicated.

Gastric analysis reveals a normal or nearly nor-

FIG. 274-5. Giant rugal hypertrophy presenting the appearance of a neoplasm in a 47-year-old man with melena. Microscopic examination revealed a thickened mucosa with elongated, cystically dilated gastric glands. There was no evidence of malignancy.

mal response to histamine. The diagnosis may be confirmed by biopsy, either by suction tube or in conjunction with gastroscopy. As in carcinoma of the stomach, these patients may have significant hypoalbuminemia due to exudation of serum albumin from the hypertrophic rugae into the lumen of the stomach. In many instances, differential diagnosis cannot be made without laparotomy.

FUNCTIONAL DYSPEPSIA

While it is true that a high percentage of patients with symptoms of indigestion demonstrate gross and microscopic evidences of chronic, superficial, or atrophic gastritis, many individuals with these complaints have no alteration of the mucosa at all, conversely, many individuals with no complaints are found to have changes of acute or chronic inflammation.

Repeated studies have shown that emotion has a powerful effect upon the motor activity of the stomach, which raises the question of the relationship of emotional factors to the symptoms of patients with chronic gastritis. Reaction to life stress may satisfactorily explain the symptoms in many patients who are able to relate them to periods of emotional strain. Perhaps the fullness or heaviness is due to failure of normal gastric emptying. Scant data are available on this point; however, from Wolf and Wolf's studies on the fistula subject, Tom, we have learned that during periods of fear, defecation, or sadness gastric activity was diminished (see Chap. 272). Such decrease in gastric motor function also is an accompaniment of nausea, which, with increased pressure in the duodenum, has been provoked by the technique of "stressful interview." Although no evidence exists that prolonged tension induces changes of superficial gastritis, intense resentment and anger may be associated with marked hyperemia and friability.

Functional dyspepsia is usually chronic; the majority of these patients will be plagued by their symptoms indefinitely, but will respond at times to strong reassurance, judicious sedation, and empiric alteration of diet.

OTHER MALIGNANT TUMORS OF THE STOMACH

Sarcoma. These malignancies comprise about 3 per cent of all stomach tumors; the lymphoma group (lymphosarcoma, reticulum-cell sarcoma, Hodgkin's disease, and "lymphoblastoma") is about three to four times as common as the rest. The mean age of onset is about 10 years younger than for carcinoma, but the symptoms are quite similar—pain, anorexia, weight loss, and anemia due to

blood loss. Physical examination may reveal a mass, a differential point is the splenomegaly which is present in some, but not in the majority, of instances of primary gastric lymphoma. Massive bleeding complicates the course more commonly than it does in carcinoma. Achlorhydria is found in 60 to 70 per cent.

The lymphomas tend to be locally invasive, and blood-borne metastases are less likely than for the other sarcomas.

Differential diagnosis of lymphoma may occasionally be aided by the occurrence of other systemic symptoms and signs of the process, particularly fever and lymphadenopathy.

X-ray appearance of sarcoma is easily confused with that of carcinoma, since infiltration, ulceration, distortion, etc., are commonly found in this condition; however, these lesions, particularly lymphosarcoma, may appear in a minority of instances—about 20 per cent—only as enlarged folds, without a discrete mass (Fig. 274-8). Occasionally, a submucosal tumor mass may indicate presence of a malignancy of smooth muscle origin. Diagnosis of lymphosarcoma may be made occasionally either by gastroscopic or suction biopsy; however, resection of the tumor is, of course, the principal method of diagnosis.

Surgical excision, followed by irradiation, is the treatment of choice. Such combined therapy results in 5-year cures in excess of 25 per cent. It is well to remember that not all lymphomas are equally radiosensitive; for example, reticulum-cell sarcoma is more resistant than the small-cell variety.

Leiomyosarcoma, fibrosarcoma, neurogenic sarcoma, neurofibrosarcoma, and myxosarcoma comprise a group of rare malignant tumors of the stomach. Leiomyosarcoma is the most common and constitutes 1 per cent of all malignancies of the stomach. The others are all very rare tumors.

These lesions most often involve the greater or lesser curvature and are usually well circumscribed and pedunculated. Radiologically, they may appear as circumscribed globular filling defects or submucosal tumors with ulceration of the overlying mucosa.

Melena or hematemesis is the most common presenting complaint. Anorexia, indigestion, weight loss, and obstruction may be present, but much less often than in carcinoma or lymphoma. A mass is frequently palpable.

Leiomyosarcoma does not appear to arise from a preexisting benign leiomyoma. Clinically and grossly it is difficult to distinguish between leiomyoma and leiomyosarcoma. Histologic study is necessary.

These tumors metastasize locally and less frequently than carcinoma. The treatment of these

sarcomas is radical surgical removal. A great majority of cases undergoing exploratory laparotomy are found to be operable, and the 5-year survival rate after surgery is between 45 and 55 per cent. Ten-year survivals are not at all uncommon.

BENIGN TUMORS OF THE STOMACH

The incidence of benign tumors of the stomach in an adult population is estimated at about 0.4 per cent. These neoplasms may be divided according to origin into epithelial (60 per cent), mesenchymal (32 per cent), and ectodermal (8 per cent).

Epithelial. These tumors are polypoid adenomas, most of which are asymptomatic. The majority are located in the antrum and frequently are multiple. Over 75 per cent of cases have associated achylia-dria (following test meal or histamine). Clinical importance centers upon potentiality for malignant degeneration, particularly when associated with pernicious anemia (Fig. 274-4), which is present in about 10 per cent of the entire group. The exact incidence of malignant transformation is not precisely known; however, evidence indicates it to vary from 7 to 22 per cent. In those patients with symptoms, pain and bleeding are most prominent. Preoperatively, diagnosis may be made only by

FIG. 274-7. Large leiomyoma of the stomach.

x-ray or gastroscopy. Local resection of the lesion is the treatment of choice. If large, multiple, or malignant, partial or total resection becomes necessary.

Mesenchymal. These include *leiomyoma*, *fibroma*, and *lipoma*. *Leiomyoma* is the commonest of this group, comprising 25 per cent of all benign tumors. It may be situated in any area, is always submucosal, frequently ulcerates, and may bleed massively. Occasionally, the patient will complain of pain in the epigastrium. Diagnosis is established by x-ray; however, small tumors may easily be overlooked. Indeed, tiny mesenchymal tumors are found commonly at autopsy. The typical appearance of such a neoplasm is illustrated in Fig. 274-7. A small percentage seem to undergo malignant change, but proof on this point is lacking. Treatment is surgical removal, necessitating local or partial gastric resection in all instances.

Fibroma is a rare benign gastric tumor constituting about 5 per cent of the group, and in the vast majority of cases is asymptomatic and, therefore, is an incidental finding at laparotomy or autopsy. *Lipoma* is an extremely rare and usually asymptomatic tumor.

Ectodermal. *Neurofibroma* is the principal ectodermal tumor. Pain and/or bleeding are often noted. Diagnosis is frequently made only by surgical exploration.

MISCELLANEOUS DISEASES OF THE STOMACH

Prolapse of the Gastric Mucosa. Prolapse of the gastric mucosa is a herniation of a portion of gastric

FIG. 274-8. Lymphosarcoma of the stomach. Note infiltration, enlargement of folds of this tumor.

mucosa through the pylorus, resulting in a characteristic roentgen appearance. It may occur at any age, but is usually seen in the fifth decade, and is seen in 2 to 14 per cent of patients subjected to examination. The cause is unknown but is thought to be due to hyperperistalsis associated with local inflammation and excessive mobility of the mucosa upon the muscularis.

This condition usually is asymptomatic and is discovered as an incidental finding. The symptoms attributed to this condition—epigastric distress, nausea, vomiting, weakness, weight loss, and occasionally bleeding—are nonspecific and are probably caused by an accompanying gastritis, peptic ulcer, or spasm.

The diagnosis of prolapse is suggested by the roentgen demonstration of (1) an "umbrella" or "mushroomlike" filling defect in the base of the duodenal bulb and (2) rugae extending through the pylorus into the duodenal cap. If symptoms are present, a bland diet with antispasmodics may be prescribed, but frequently is ineffective. Results of surgery are not clear. Subtotal gastric resection is occasionally necessary if bleeding is severe.

Foreign Bodies in the Stomach. A wide variety of foreign bodies may be found in the stomach. Small objects such as coins and marbles accidentally swallowed by children rarely cause symptoms and eventually pass through the gastrointestinal tract. Sharp-pointed objects (pins, needles) may penetrate the wall of the stomach or intestine, producing peritonitis or an abscess. Large foreign bodies (spoons, knives, forks) found in the stomachs of the insane usually produce no symptoms, although ulceration, perforation, or obstruction may occur.

Bezoars are conglomerations of swallowed foreign material consisting of hair (trichobezoar), hair and vegetable fiber (trichophytobezoar), or vegetable fiber alone (phytobezoar). The prolonged use of calcium or magnesium powders may give rise to concretions in the stomach (gastroliths). Bezoars may attain a large size, producing symptoms simulating gastritis, peptic ulcer, cancer, or pyloric obstruction. They may occasionally simulate malignancy during roentgen examination. Significantly, these masses are found almost exclusively in severely disturbed or psychotic individuals.

Treatment is indicated only when definite symptoms are present or when the foreign body presents a mechanical hazard. Laparotomy with surgical removal may then be necessary.

Syphilis of the Stomach. Although extremely rare, this disease must be considered in any individual with active or latent lues who has epigastric pain, vomiting, weight loss, or bleeding. X-ray of the stomach may reveal one of several abnormali-

ties: (1) filling defect or localized infiltration without a mass, (2) "hourglass" stomach, and (3) diffuse involvement of the wall. Differentiation, therefore, from carcinoma of the stomach is almost impossible, and surgical exploration is recommended. Response to antiluetic therapy is dramatic, but the x-ray appearance may change only very slowly.

Tuberculosis of the Stomach. Tuberculosis infection of the stomach is rare and is almost always associated with disease in other organs, particularly the lungs. The lesion may be infiltrative, granulomatous, or ulcerative. Symptoms are the same as those noted in carcinoma, benign ulcer, syphilis, etc. Diagnosis can be made only by examination of tissue obtained at laparotomy. Antituberculosis therapy (isonicotinic acid hydrochloride and streptomycin) is usually effective in those rare instances in which the diseased portion is not resected.

Fungal Infections of the Stomach. Fungal infections of the stomach include actinomycosis, moniliasis (*Candida albicans*), aspergillosis, and many others. These infections frequently produce superficial or deep ulcerations of the stomach, which may be single or multiple, although they rarely penetrate or perforate. The symptoms simulate those of gastritis, ulcer, or malignant disease of the stomach. Examination of the vomitus or the gastric contents may reveal the fungus. Treatment is that for fungus infections in general.

Acute Dilatation of the Stomach. Acute dilatation of the stomach is characterized by a rapid accumulation of large quantities (2,000 to 4,000 ml) of gastric and intestinal juices with marked gaseous distention of the stomach.

Etiology. The cause of the disorder is unknown. It usually occurs as a sequela of abdominal or pelvic operations, or it may follow abdominal trauma, severe injury, parturition, or overeating. At times it is associated with severe diabetic acidosis. It may complicate an acute infectious disease or be associated with uremia or marked electrolyte disturbances, particularly potassium deficiency. Since gastric intubation, particularly after abdominal surgery, has become widely used, acute dilatation is rarely encountered after laparotomy.

Acute dilatation of the stomach has been attributed to the reflex inhibition of the gastric motor mechanism through efferent impulses reaching the stomach by way of the vagi and splanchnics. The primary defect appears to be a loss of gastric tone followed by the swallowing of air and the accumulation of gastric and duodenal secretions which cannot be reabsorbed.

The onset is often insidious. During the first 24 to 48 hr there is marked apathy and listlessness or epigastric fullness and constipation, rarely with severe pain. The epigastrium progressively increases in size, but regurgitation and vomiting may not

appear until tremendous distention has developed. Although vomiting may be copious, the stomach cannot empty completely. Visible gastric peristalsis is absent because of gastric atony; a succussion splash may be elicited. Dehydration ensues, associated with hypochloremic alkalosis, tetany, and uremia as a result of electrolyte imbalance. Profound prostration, collapse, shock, delirium, coma, and death follow.

The flat film of the abdomen reveals a markedly dilated stomach filled with air and fluid. Treatment consists of continuous gastric suction for one day or more, administration of parenteral fluids, and correction of serum electrolytes, particularly potassium deficiency, as discussed in the section on pyloric obstruction. The patient usually recovers if treatment is instituted promptly.

CONGENITAL ANOMALIES OF THE STOMACH

Congenital Hypertrophic Pyloric Stenosis of Infancy and Adulthood. This disease is characterized by (1) hypertrophy of the pyloric muscle, particularly the circular muscle layer; and (2) spasm resulting in narrowing of the pyloric channel. There is no histologic evidence of inflammation. Boys are affected four times as commonly as girls. Rarely, incomplete congenital stenosis may become asymptomatic in adults.

Symptoms. Regurgitation and periodic vomiting herald the onset, usually from 2 to 3 weeks to 2 to 4 months after birth. The vomiting is often projectile, without retching, and is followed by rapid weight loss, constipation, and dehydration. In the adult form, intermittent but progressive vomiting, which may appear at any age, dominates the clinical picture.

Diagnosis. Physical examination reveals visible hyperperistalsis, dehydration, and malnutrition. In infants, a mass the size of an olive may be felt at the right rectus border beneath the costal margin. In doubtful cases, that is, when a tumor is not palpable, x-ray examination should be done, using water-soluble radiopaque substances such as Myokon, which, unlike barium, will not plug the pylorus or cause serious pulmonary damage if aspirated. This usually demonstrates some enlargement of the stomach with delayed gastric emptying and an elongated, narrowed, pyloric segment. Diagnosis is made in adults by roentgenographic examination, which reveals the same changes of the pyloric canal as noted in infants. Figure 274-8 is the roentgenogram of a middle-aged woman with recurrent vomiting of many years' duration, which had never previously been investigated. Pyloroplasty resulted in complete relief.

Treatment. A trial of medical management with

FIG. 274-8. Congenital hypertrophic stenosis in a 53-year-old woman with recurrent vomiting.

frequent small feedings, antispasmodics, and correction of electrolyte and fluid imbalance may be instituted when the history is not clear and if a mass is not palpable. Once the diagnosis is made, however, the Ramstedt operation, which consists of a longitudinal incision through the pyloric muscle to the mucosa, and which is uniformly successful, should be performed. The same approach is recommended when the diagnosis of pyloric stenosis is made in an adult.

Diverticula of the Stomach. A gastric diverticulum is an outpouching or protrusion of the stomach wall, forming a permanent sac. True diverticula contain all the muscular coats within the wall of the pouch and are usually congenital. False diverticula are acquired, and they lack the muscular coats.

Incidence. Both congenital and acquired gastric diverticula are most often seen in middle-aged women. The posterior wall of the cardia near the lesser curvature is the most common site for the congenital type. Acquired gastric traction diverticula are found most often near the pylorus and are caused by inflammatory or malignant involvement of adjacent organs. The former variety is almost always asymptomatic. Surgery may be required for the condition which underlies the acquired type.

275 DISEASES OF THE DUODENUM AND SMALL INTESTINE

Albert I. Mendeloff

DIVERTICULOSIS

It is usually impossible on clinical grounds to decide whether diverticula of the intestinal tract are congenital or acquired. The rarer congenital diverticula contain the entire thickness of the intestinal wall, whereas acquired diverticula consist of mucosa and serosa alone. Probably the defect in the muscular wall through which the mucosa herniates is always potentially present, usually at the points where the nutrient arteries perforate the serosal and muscular layers. As with other forms of herniations, these potential tunnels are widened as life proceeds, so that all forms of diverticulosis are more common among persons in the later decades of life. Some individuals display great numbers of diverticula of the gastrointestinal tract, from esophagus to anus, but more often diverticula of the stomach and small intestine are solitary; they are more common in the duodenum (possibly 5 per cent of all persons having barium studies of this area), next most frequent in the jejunum, and rare in the ileum, except for Meckel's diverticulum. Colonic diverticula are more common than small intestinal diverticula, and are always multiple.

Diverticula of the Duodenum. These are most commonly found on the medial surface of the second portion of the duodenum, in close proximity to the entrance of the pancreatic and common ducts. They are usually wide-necked, about 1 cm in diameter, and appear to fill with and expel intestinal contents with ease. Occasionally on intubation studies of the second duodenum one aspirates undigested food particles, which must of necessity represent gastric chyme trapped in these diverticula and protected from digestive action.

The location of duodenal diverticula constitutes the main reason for suspecting their pathogenicity. Although statistically few patients harboring these common outpouchings suffer any misfortune from their presence, there are documented cases in which obstruction to the neck of the diverticulum has led to acute diverticulitis, hemorrhage, and necrosis of the wall; pressure exerted by obstructed diverticula on pancreatic ducts has definitely resulted in acute pancreatitis, pressure on the common duct in obstructive jaundice. When diverticula occur along the third portion of the duodenum they have occasionally been the site of acute inflammation and free perforation, with consequent peritonitis.

Diverticula of the Jejunum. Although less common, these seem to be more subject to the development of acute inflammation and necrosis of the wall, with severe upper abdominal pain and occasionally massive intestinal hemorrhage ensuing. The acute process may go on to suppurate, a definite mass and localized peritonitis are the accompanying physical findings. Another way in which multiple diverticula of the jejunum may result in disease is the effective replacement of normal absorbing jejunal surface by multiple bacteria-filled sacs, resulting in a characteristic malabsorption syndrome due to loss of surface and competitive loss of nutrients to the saprophytic bacteria in the diverticula (Fig 275-1) (see Chap. 62).

Meckel's Diverticulum. Resulting from persistence of the omphalomesenteric duct, this diverticulum is reasonably common, occurring in about 3 per cent of all laparotomized children in whom a definite search is made and in about 2 per cent of autopsied adults. Even though only a small percentage of these diverticula cause trouble, the possibility must be thought of in every case of gastrointestinal hemorrhage and obstruction. The diverticula are usually found on the antimesenteric border within the last 90 cm of the ileum, and most frequently within 50 cm of the ileocecal valve. They may be wide-mouthed or narrow, short or long, sometimes a nubbins hard to find on the smooth surface of the ileum, occasionally a long 10- to 20-cm funnel attached like a stout pipe to the umbilicus. Diverticula lying within the mesentery are rare and do not arise from the omphalomesenteric duct. The diverticulum may be lined with normal ileal mucosa, or it may contain varying amounts of ectopic gastric, pancreatic, duodenal, or colonic epithelium. Symptoms are more common in males by at least 3:1. Coincident malformations are infrequently met. There is no hereditary pattern. In children and adolescents, bleeding from this epithelium is the striking clinical feature, with or without the presence of a palpable mass. The source of bleeding is almost invariably an ulcer-

tion, and this is generally of peptic origin. The gastric mucosa in the Meckel's diverticulum has been shown to secrete acid peptic juice, which acts on bordering ileal epithelium to produce the ulcer. Pathologically the ulcer is always near the junction of gastric and ileal mucosa, on the ileal side; it thus resembles the usual anastomotic ulcer occurring after gastrojejunostomy. In the young adult the clinical picture begins to change, inflammatory processes becoming more prominent, and varying degrees of intestinal obstruction, either of the ileum proximal to the diverticulum or of neighboring loops of bowel trapped behind the inflammatory mass, constitute the most serious presenting symptoms. Free perforation of Meckel's diverticulum is relatively uncommon, but sealed-off localized perforations are very common once the initial inflammatory process has distorted the bowel enough to set up the pathologic requisites for cyclical bouts of inflammation. A number of these patients have repeated bouts of low-grade abdominal cramps referred to the infraumbilical area, usually aggravated by eating. The diagnosis is rarely made by x-ray studies of the small or large intestine, but these are necessary in order to eliminate other possible lesions. The treatment is entirely surgical.

DUODENITIS

When a patient presents the symptoms and signs of peptic ulcer (Chap. 272) but the radiologic examination of the duodenum demonstrates no localized ulceration or deformity, but rather coarsely irregular mucosal folds from the duodenal bulb well down into the junction of the second and third portions of the duodenum, with irritability of the area, that patient is said to be suffering from peptic duodenitis. The incidence of this disease is not known, since radiologists vary in their willingness to apply the label to persons displaying minimal abnormalities of this type, but it is probably a common disorder, closely related in every way to the classical disorder—duodenal ulcer—of which it is the frequent precursor. Often the irritability and edema of the area prevent visualization by x-ray of a small ulcer crater, which may be the source of a severe hemorrhage, and thus the duodenitis is said to be the source of the hemorrhage. In terms of the host factors and the environmental stresses now well-identified as important in the genesis of peptic ulcer of the duodenum, these patients are in no way different from those suffering from the latter disease and respond in characteristically favorable ways to the medical regimen employed in treating the patient with duodenal ulcer.

Occasionally one notes on radiologic examination a cobblestoned appearance of the duodenal bulb caused by hypertrophy of Brunner's glands,

FIG. 275-1. Multiple diverticula of jejunum in 55-year-old man with macrocytic anemia.

deep structures secreting an alkaline mucoid material of unknown function. Most authorities regard this hypertrophy as of no clinical significance, but occasionally it is associated with the symptoms of duodenitis.

MOTOR DISTURBANCES

Obstructive Syndromes. The natural tendency of smooth muscle when operating against a pressure gradient is to stretch and contract forcibly. This increased distention is pain-producing (see Chap. 6, Acute Abdominal Pain). Thus all syndromes in which normal small bowel is trying to force luminal contents past nonrelaxing segments of more distal bowel, whether occasioned by a tumor, a stricture, an occluding gallstone, or a constricting band, are primarily characterized by painful cramps at the onset, progressing to loss of pain sensation as the bowel loses its viability. Associated with the progress of events are many others which may assume prominent roles in coloring the symptoms evoked. Intermittent jejunal or ileal obstruction, with poor maintenance of oil-water interfaces, will lead to malabsorption (see Chaps. 82 and 276).

Motor abnormalities of the duodenum associated with many psychic disturbances (e.g., anorexia nervosa) or with generalized disorders such as lupus erythematosus may result in severe bouts of nausea and vomiting. The radiologist may get the impression of an organic obstruction of the third

portion of the duodenum at the point at which the superior mesenteric vessels cross anterior to the gut. Such impressions have given rise to many diagnoses of "mesenteric root compression syndrome" which fail to be borne out on surgical exploration to remove the source of the obstruction. It is important to understand that an atonic or sluggish duodenum proximal to this "compressed" area will of itself produce the apparent obstructive picture, just as gastric atony may make a normal pyloric area appear to be "obstructing." Only if the peristaltic activity of the first and second portions of the duodenum is normal or hyperactive can one suspect an organic obstruction of the third portion of the duodenum. If this is identified, exploration is indicated and a bypassing operation justified.

Stasis. Complete stasis of the duodenum occurs rarely, usually in association with mesenteric vascular catastrophes. On x-ray examination, dilatation of the duodenum with a peculiar churning of the barium meal is characteristically noted in the patient with anorexia nervosa and, occasionally, in those suffering from severe ulcerative colitis. Elsewhere in the small intestine, stasis is the result of loss of vascular integrity, an exhaustion following mechanical or paralytic ileus (Chap. 276).

Spasm. Spasm of the duodenum occurs in peptic disorders, acute pancreatitis, or in various conditions associated with severe nausea. Experimental nausea, as, for example, that produced by vestibular stimulation, gives characteristically a tetanic spasm of the duodenum.

Pain. Migratory or steady pain around the umbilicus may result from insufficiency of the mesenteric vessels, usually as a result of degenerative aortic disease encroaching on the lumina of the vessels.

REGIONAL ENTERITIS

The most disabling and discouraging affliction of the small intestine known to the internist is regional enteritis, an unpredictable granulomatous response of the submucosa to an unknown agent or agents, in which damage is done by encroachment upon the lumen, scarring of the muscle, ulceration of the mucosa, and necrotic breakdown with fistula formation between loops of bowel, bowel and skin, and bowel and perirectal spaces. Any, all, or none of these sequelae may follow the initial bout of the disease, and single attacks are well documented. Much more common, however, is recurrence and slow spread of the lesion to involve contiguous areas of the intestine, including occasionally the duodenum. Involvement of the antrum of the stomach by a similar process has been described.

Since the original description by Crohn, Cin-

burg, and Oppenheimer in 1932, in which this disorder was localized to the terminal ileum, a number of different clinical syndromes have been distinguished from the classical forms, but our knowledge is far from satisfactory as to causes, course, and proper management.

Epidemiology. The disorder is world-wide in distribution, and occurs among all races. In the United States its exact incidence is unknown, but it appears to be about one-fifth as common as chronic ulcerative colitis. It has been reported as having its onset in every decade of life, but it is characteristically a disorder of young adults, the peak incidence being between the ages of fifteen and thirty-five. Both sexes are affected with equal frequency; Negroes are less commonly affected than whites.

The affected subjects are more often of Jewish origin than one would expect by chance; in some series Jews appear to be about three times as commonly involved as their distribution in the population at large would suggest. The patients show urban backgrounds more commonly than rural, reach higher levels of schooling than usual and slightly higher economic status than ordinarily encountered. Despite some evidence to the contrary, severely disturbed personalities are not routinely met with in these patients, particularly early in the course of the disease or antedating the onset of the disease. Many such patients show remarkable fortitude in meeting the innumerable difficulties wrought by progressive destruction of the intestine; a number have distinguished themselves in the arts, sciences, professions, and business despite prolonged and progressive disease.

Familial occurrence of the disease has been recognized from the onset. In various series the percentage of cases occurring in siblings ranges from 2 to 10; father-daughter, mother-son, and father-son patterns are recorded in all large series of cases. The onset of disease in the child does not exhibit anticipation, and other associated stigmas are so rare as to make it unlikely that genetic factors are of more than predisposing importance.

Etiology and Pathogenesis. No specific cause of this disease has been identified. Investigations have been carried out on the possible etiologic relationship of bacterial and viral organisms identified more frequently in the gastrointestinal tract of these patients than in normal subjects, but all such studies have been fruitless. Certain disorders of the mesenteric arteries seen in the aging population have occasionally given rise to a submucosal inflammatory and cicatricial reaction producing a picture similar to that of regional enteritis, but in the majority of cases of regional enteritis no such arterial lesions can be found. The enlarged and succulent lymph nodes of the mesentery seem to result from the submucosal inflammation rather

FIG. 275-2. Regional enteritis; resected specimen of ileocecal area demonstrating the hypertrophy of ileal submucosa (right), with nodular encroachment on the lumen and minute areas of mucosal hemorrhage.

than to be its cause, remarkable alterations in the autonomic ganglia of the bowel wall, frequently seen in excised specimens, are rarely present early in the course of the disease. Histochemical studies are remarkably normal, particularly with respect to the columnar epithelium of the bowel luminal surface. Granulomatous tubercles are characteristically encountered in the submucosa, in the peritoneal reactions of serosa, and in fistulous tracts; these show giant cells in the center, but no caseation and no evidences of fungi or inclusion bodies.

The earliest lesions, as seen in the terminal ileum, are rarely minute, and more usually involve appreciable (8 to 20 cm) lengths of gut in a swollen beefy glistening mass, occasionally rather purplish, but more often intensely red. The serosa is often injected and the mesenteric fat edematous. Large lymph nodes in the mesentery nearby are commonly noted. The luminal surface of the bowel is thrown up into injected folds stretched over the heaped-up submucosal hypertrophy (Fig. 275-2). Ulceration of this mucosa, although common, is usually superficial in the early stages of the disease, when microscopically the nonulcerated areas of mucosa appear healthy.

There is usually a definite demarcation between the diseased and healthy bowel; the appendix may

be involved by a similar process or may merely show lymphoid hyperplasia and venous congestion as a result of the adjacent inflammatory reaction. The initial process may disappear rather quickly, may remain indolent only to flare up months or years later, or may slowly progress to involve ileal segments more cephalad. "Skips" are well-documented, in which an initial ileal lesion subsides, and a midjejunal lesion of similar character develops later, the intervening area remaining uninvolved. Adjacent or contiguous small or large intestine may be involved, if not invaded, by this inflammatory process; cicatrization, local perforations, abscesses, and fistulas commonly characterize the development of such a process. The fistulas may go from intestine to colon, from intestine to skin, or from one loop of intestine to another. Loops low in the pelvis or involving sigmoid colon often produce perirectal or ischioirectal abscesses, perirectal nodular masses seen on proctoscopy, or proctitis. A number of changes—endothelial cell proliferation in lymphatics, giant cell aggregations in the edematous submucosa, ischemic contraction of smaller arterioles, and increased numbers of ganglion cells and neurofibrillar accumulations—occur characteristically in surgical and autopsy material and in such profusion as to render the patho-

logic diagnosis of the disease easy to make. However, the primacy of any one of these changes, or even the proper sequence of lesions, is not clear.

The endothelial reaction in lymphatics and the presence of granulomas as the principal tissue reaction have suggested to many that the disease must be a reaction to some irritant absorbed in the lymphatics, the absence of foreign bodies in the giant cells would lead one not to suspect particulate foreign matter as the offending agent; attempts have been made to produce the disease experimentally by abnormal fatty substances, but so far these studies have been fruitless. There is little evidence that the succulent lymph nodes seen in the mesentery of cases of early acute ileitis are more than a phase of acute secondary lymphadenitis, rather than a reflection of an etiologic primary lymphangitis. Sarcoidosis, tuberculosis, and reaction to abdominal trauma seem unrelated to the characteristic forms of this disease, even though some of the granulomas may be indistinguishable from the characteristic lesions of these processes.

Symptoms. These depend on the location of the inflammatory lesion, its extent, its acuteness, the amount of obstruction it produces, the peritoneal reaction, if any, and its relationship to contiguous structures. A certain number of such patients may present only with the systemic features of a febrile illness without localizing symptoms or signs. Even in these cases, a careful history will often document abdominal discomfort, loose stools, rectal urgency, and mild anorexia made worse by the feeling that abdominal discomfort increases after eating.

Acute ileitis presents as the sudden development of right lower quadrant pain and tenderness, with fever, localized guarding, and some disturbance of bowel motility—either diarrhea or constipation. It thus presents the clinical picture of appendicitis, and the differential diagnosis can be made only at laparotomy, when the characteristic beefy red terminal ileum, boggy mesenteric fat, and succulent lymph nodes of the mesentery tell the surgeon that appendicitis alone could not produce the picture. The appendix also may be involved in the primary lesion, or may be obstructed secondarily by the acute submucosal edema of the adjacent ileitis.

In one large series, diarrhea, colicky pain, and weight loss were encountered as presenting symptoms in over two-thirds of 600 patients. Fever occurred in one-third, and a history of bright red rectal bleeding or melena in less than one-sixth. Symptoms related to rectal and anal complications predominated in about 10 per cent.

Approximately half the patients have initial involvement of the terminal ileum, another 15 per cent have both ileum and cecum affected at the

onset, and less than 4 per cent present initial symptoms due exclusively to jejunal or duodenal involvement. Various other combinations of jejunal, ileal, and colonic lesions may be seen at the time the patient first consults the physician.

Variants of this picture include (1) a full-blown *malabsorption syndrome* (Chap. 62) with any one or many malnutritive derangements capturing the spotlight, (2) *acute perforation* and *generalized peritonitis* (less than 1 per cent), or (3) *massive melena*, seen in less than 2 per cent of cases. The advanced case, with cutaneous fistulas, easily appreciable masses throughout the abdomen, increased pigmentation, and severe proctitis, presents little difficulty in diagnosis. Amyloidosis due to regional enteritis is becoming a more frequent complication and may be responsible for the patient's death in renal failure.

As experience with the disease as a whole has expanded, a certain number of patients have been encountered who present a diffuse involvement of jejunum and ileum when first seen. These patients have been described by Crohn as having a subtype of regional enteritis in which the lesions are more superficial but much more extensive, less prone to suppurative complications and fistula formations, but likely to lead to malabsorptive symptoms, fever, splenomegaly, and clubbing of the fingers, the reasons for which are not understood.

On physical examination these patients with enteritis characteristically display various evidences of undernutrition and malnutrition. If the symptoms are of long standing. Clubbing of the fingers is frequent in this group. Special attention to the abdominal examination is necessary, since a definite mass or doughy aggregations of bowel loops can be felt in one-third of the patients. Fistulous tracts between the involved bowel and the abdominal skin are classical complications of the disease and are easily appreciated. More readily overlooked are the perirectal and ischiorectal fistulas found in nearly 10 per cent of chronic cases; rectal digital examination will disclose an anorectal stricture in half of these cases and in 3 to 4 per cent of those without fistulas. Proctoscopic examination is abnormal in 10 to 15 per cent; the abnormalities may include nodular submucosal masses, acute proctitis, ulceration, or stricture in the rectosigmoid junction. Rectovaginal fistulas are noted in a small percentage of cases.

Diagnosis. Regional enteritis should be suspected on clinical grounds in most instances when a patient presents with a history of intermittent chronic diarrhea, fever, weight loss, crampy pain or distention, and on physical examination shows perianal suppuration, anal strictures, and abdominal masses. It should be part of the differential diagnosis of all types of malabsorption (Chap. 62), fever

of unexplained origin, intermittent small bowel obstruction, and secondary amyloidosis.

Laboratory features of regional enteritis parallel the severity of the (1) inflammatory reaction: leukocytosis, elevated sedimentation rate; (2) blood loss by ulceration: iron deficiency anemia; (3) undernutrition and malabsorption: hypoalbuminemia, hypocalcemia, hypokalemia, elevated serum alkaline phosphatase, hypoprothrombinemia, and macrocytic anemia; (4) possibly more specific changes related to disturbed protein metabolism: elevated serumucoids in the serum and hypergamma-globulinemia. None of these laboratory tests is diagnostic.

The most helpful adjunct to the clinician suspicious of regional enteritis is the radiologist, who generally establishes the diagnosis short of histologic confirmation. Marshak and Wolf have tried to separate the nonstenotic phase of regional enteritis from the stenotic phase on radiologic grounds, despite the fact that occasionally both phases may be encountered in the same patient. In the nonstenotic phase the principal changes are loss of detail in the mucosa, stiffening of the submucosa to form a tubular pattern on the radiograph, and separation of the tubular loops by inflammation in the mesentery. The stenotic phase is characterized by narrowing of the lumen, with dilatation of normal bowel proximally. In the dilated area poor oil-water interfaces and retained mucus secretions produce abnormal puddling of the barium. Fistulous tracts are often seen, particularly in the ileocecal area, and are practically diagnostic, the only other disease likely to produce a similar picture being actinomycosis. When the duodenum or upper jejunum is involved by regional enteritis, the stenotic phase predominates from the onset, whereas ileal involvement characteristically is nonstenotic and ulcerative early in its course (Fig. 275-3). The unoperated case usually demonstrates little radiologic change after the first studies are completed, except for fistula formation.

Definitive diagnosis on histologic grounds is established under the microscope, although most surgeons can make an accurate diagnosis by inspection at the operating table of the beefy reddish-to-bluish serosa, edematous mesentery, and large lymph nodes. Differential diagnosis in the operating room includes tuberculosis, various lymphomas, sarcoidosis, and fungous diseases. Biopsies of the bowel and lymph nodes provide adequate bases for histologic diagnosis.

Course and Prognosis. Acute regional ileitis apparently is self-limited in about a third of the cases; the other two-thirds go on to develop chronic enteritis, and it is possible that 10 to 15 per cent of all cases of regional enteritis are outgrowths of an original acute ileitis.

FIG. 275-3. Regional enteritis: several involved loops of ileum communicate via multiple fistulous tracts. Small bowel proximal to involved areas is dilated (upper).

Accurate prognostication in this disease is at present impossible, largely because there exists no large body of cases treated entirely supportively in the atmosphere of a sanatorium. Almost every large series of cases consists of a heterogeneous population of enteritis of different longevity, severity, and past nutritional and pharmaceutical experience, 90 per cent of whom require surgery for some complication of the original disease. Our prognostications, then, must be made on the basis of surgically treated patients subjected to a wide variety of therapeutic procedures at widely varying periods of disease, with interim periods of varying supportive therapy. The extent of the intestinal lesions in an unoperated case tends to remain that present when the patient was first seen, except for the development of fistulas. If operation is carried out to remove the entire diseased bowel, as was the custom soon after the disease was first identified, approximately half the cases have a recurrence of the disease within a few years of the operation. Whether this is due to failure at operation to recognize "skip" areas of enteritis proximal to the resected area, or whether new foci of enteritis develop in hitherto normal bowel is not clear. In any case, the physician should expect a patient with regional enteritis to have exacerbations and remissions over a period of many years; these exacerbations usually involve the same areas of

bowel established as diseased in the first attack, but ulceration, fistulas, and stenosis may supervene at any time. Extension of these suppurative and necrotic lesions to neighboring loops of small bowel, colon, bladder, and perirectal tissues may be constantly suspected and looked for by the physician.

Involvement of the colon by a granulomatous inflammatory process is reported by some workers in half their cases of enteritis, but most investigators believe that a true granulomatous colitis is seen in only a small percentage of enteritis cases. Minimal involvement of the colon by fistulas and masses does not produce granulomatous reactions in the colon, but occasionally true ulcerative colitis is seen in the colon when indubitable regional enteritis is present in the small intestine.

Involvement of more distant organs and organ systems unrelated to the intestine has been reported with increasing frequency as these patients have been studied more closely over a long time span. Liver abnormalities and nodular pancreatitis have been reported, but their relation to the primary disease is dubious in view of the transfusions, injections, and drugs these patients receive and of the many nutritional deficiencies they incur. More significant is the incidence of arthritic symptoms which also are noted in a proportion of cases of ulcerative colitis. The arthritis involves larger joints and is often of the spondylitis type; under any circumstances it is not accompanied by the laboratory data suggestive of rheumatoid disease.

Treatment. In a chronic disease of unknown cause and unpredictable course, medical management of the most comprehensive type is mandatory. Regardless of the validity of the theory that psychiatric disorder underlies or determines the onset and progression of this disease, it is clear that careful attention to personality factors must proceed *pari passu* with meticulous attempts to meet the nutritional requirements of these patients. These must be combined to assure physical and mental rest as part of the program for combating the discouraging periods during which all efforts of physician and patient seem unable to slow the progress of the process. Psychiatric assistance will be needed in evaluating a number of these cases and should form the principal management in a small percentage. Supportive care consists first of all in explaining to the patient the problem which faces him, the relatively limited areas in which pharmacologic and surgical maneuvers can aid him, and yet at the same time repeatedly pointing out that adequate hyperalimentation, rest, and the more specific measures can enable him to "ride out" the disease; it is generally true that the activity of the disease does slow down after a number of years, at which time the patient will have residua demonstrable on x-ray and physical examination, but will be able to lead

a reasonably normal life. For women it should be made clear that pregnancy is not something to avoid; many women with severe ileitis but with a genuine wish to have children have produced normal offspring without undue hazard to themselves. Even menstrual function seems preserved better in the women with ileitis than in those with ulcerative colitis.

Specific Measures. Chemotherapeutic and antibiotic drugs are of assistance in managing the purulent complications of enteritis but have little or no effect on the primary disease process. Non-absorbable sulfonamides have been the most beneficial of these agents.

Hormonal treatment with ACTH and with various adrenal steroids has been largely unavailing. Although many of the secondary manifestations of the disease, in particular arthritis, erythema nodosum, iritis, have cleared up quickly after the institution of such therapy, the primary intestinal lesion remains unaffected. Their use may be highly efficacious in managing the rare toxic episodes characterized by high fever, severe anorexia, and depression, but constant caution must be exercised that perforations and peritonitis are not masked by this therapy.

Radiation therapy was originally proposed to control the inflammation and suppuration in patients whose disease was too generalized or whose condition too poor to tolerate resective surgery. In some cases dramatic improvement has been reported following general abdominal irradiation, and it is possibly a measure which has not been used sufficiently often as a therapeutic adjunct. No series have yet been reported which include a large number of early cases of the disease treated in this way.

Surgical therapy, originally used solely for the complications of a then little-understood process, has gone through a number of stages only to return full circle to its original status. In the 15 years, 1932 to 1947, surgery was thought to effect a cure of the disease, radical resection of the involved ileocecal area in the original group of patients with disease localized there was advocated as curative. As the years went by, however, not only did a high percentage of these patients return with a recurrent disease, but more diffuse lesions were encountered than at the first operation, making eradication surgically impossible. A more conservative surgical approach was then devised, essentially consisting of enterocolostomy without resection. Although the operative mortality and immediate postoperative morbidity from this procedure has been satisfactorily low, it is difficult to state that the recurrence rate among these patients is much lower (about 33 per cent) than among those treated with radical excision (about 40 per cent). Whether

these recurrences result from spread outward of foci of disease not seen at the time of operation or from some ill-understood activation of the disease process by newly contiguous bowel is not clear. Unfortunately, once a recurrence has occurred following surgery, every subsequent surgical maneuver tends to result in recurrence.

Since surgery is not curative, it has now returned to its original place in the therapy of enteritis, as a means of eliminating complications of the disease which are producing serious symptoms on their own. Among these are intermittent intestinal obstruction, blind loops leading to macrocytic anemia, ulcerating lesions in fixed stenotic bowel, and fistulas between the bowel and adjacent hollow viscera.

The sequelae of resections of the small intestine have been of considerable interest in throwing light on the mechanisms of nutrient absorption. The physician taking care of a patient with unoperated enteritis must have a good understanding of the nutritional derangements produced by the disease; when that patient has lost, in addition, a sizable segment of his small intestine by resection, the physician must be very much more alert in detecting and correcting the multitude of nutritional defects which inevitably result (see Chap. 62).

UNUSUAL DISORDERS OF THE SMALL INTESTINE

Pneumatosis Cystoides Intestinalis

This is a rare disease involving small or large intestine, predominantly the former, in a process characterized by numerous nitrogen-filled cysts under the serosa. These cysts are lined by endothelium and vary in size from 1 to 3 cm. It is generally assumed that the gas has arrived subserosally from the retroperitoneal space; presumably intestinal gas has penetrated lymphatics from the luminal surface, passed retroperitoneally, then dissected along the mesentery until it again reaches the subserosa. Obstructive lesions of the bowel are common precursors of the condition—pyloric stenosis, tumors, regional enteritis, have been specifically described.

Symptoms are primarily abdominal pain, bloody diarrhea, or the sudden onset of pneumoperitoneum from rupture of a cyst. Diagnosis is usually made radiologically, the cysts deforming the bowel lumen in a characteristic way.

Treatment is that of the underlying disease, which is generally surgical.

Whipple's Disease

In 1907, G. H. Whipple described a new disease entity marked clinically by progressive wasting, diarrhea, arthritis, and skin pigmentation. At au-

topsy the patient displayed a diffusely edematous small and large intestine supported by a mesentery full of enlarged lymph nodes. The microscopic and chemical analyses of the tissues disclosed a great increase in fat content, but Whipple noted especially the presence of large macrophages throughout the lamina propria of the gut and in the lymph nodes; these macrophages were filled with a foamy material which did not stain with lipophilic dyes; he also noted small sickle-form particles in the macrophages which took a silver stain. He called the disease "intestinal lipodystrophy."

Since 1907 the disease has been reported in increasing numbers. The clinical course is quite variable, the multiplicity of organs and tissues involved suggesting that this is indeed a generalized disturbance. The material in the macrophages is a mucoprotein; such cells have been identified in all portions of the intestinal tract, in peripheral lymph nodes, liver, pancreatic acini, spleen, bone marrow, myocardium, lungs and pleura, adrenal glands, and the hypothalamus.

The reported cases have occurred almost entirely in men; there may be a familial predisposition. The disturbed mucoproteins noted in the histochemical preparations may also be found in the serum. The disease should be thought of in any adult patient presenting with diarrhea, malabsorption syndrome, pigmentation, or polyarthritis. Diagnosis is made by biopsy of small intestine, colon, or peripheral nodes, or at laparotomy. There is no therapy of proved efficacy, although steroids and tetracycline compounds have been of temporary benefit. Spontaneous remissions have been described, but generally the disease is progressive and leads to the death of the patient.

TUMORS OF THE SMALL INTESTINE

Generally, this is an infrequently occurring group of lesions, but because of the variety of symptoms they produce, they may be very difficult to diagnose. It is perhaps best to describe them according to their pathology, since any or all of them may produce identical symptoms.

Benign Tumors

Leiomyomas of clinical significance are rare in the small intestine, but they may produce intussusception with obstruction, ulceration and hemorrhage, with fatal outcome, or varying degrees of intestinal obstruction alone. The mucosa becomes stretched tightly over these solid tumors and frequently ulcerates to produce gastrointestinal hemorrhage of mild to fatal severity. Malignant change may occur at any time.

Hemangiomas of the small intestine, although rare, are very difficult to identify by clinical

methods or radiologic examination. When they bleed suddenly into the bowel wall they often collapse, so that they do not present to radiologic study any space-occupying defect in the barium-filled bowel. They may be multiple. The occurrence of these various syndromes as hereditary disorders is well documented, and a hint as to the existence of an intestinal hemangioma may well be gleaned from identification of hemangiomas of the skin or mucous membrane (see Chap. 238).

Lipomas are more common than leiomyomas or hemangiomas in the small intestine and, like them, may be involved in developmental anomalies of supporting tissues in the bowel and elsewhere. Although a number of these could be considered to be hamartomas, they do exhibit the neoplastic ability to grow and expand. Characteristically, they are found in middle adult life, although they may have been growing slowly for many years before making clinical mischief. Sex incidence is probably equal. It is probable that they arise from adipose tissue anywhere in the body. Since the mesentery of the small intestine contains a large amount of such tissue, a variety of lipomas involving the wall of the bowel to produce obstruction have been documented.

Polypoid tumors of the small intestine usually turn out to be hamartomas. These have been thoroughly studied as part of the Peutz-Jeghers syndrome (see Chap. 98). Such tumors are rarely malignant, but may cause intussusception and hemorrhage.

Malignant Tumors

Malignant tumors of the small intestine are not common in the United States, accounting for less than 1 per cent of all digestive tract cancers. In Africa, on the other hand, primary tumors of the small intestine have been described among some races as more common than carcinoma of the stomach.

Adenocarcinoma of the duodenum is more frequent as an independent lesion than is carcinoma of the jejunum or ileum. However, in recent years diffuse carcinomas of the small bowel have been described in patients with long-standing regional enteritis. The most frequently involved area of duodenum is the second, near the papilla of Vater. The tumor usually causes ulceration with hemorrhage or high obstruction and may be easily confused radiologically with chronic peptic ulcer in the same area. Carcinoma of the jejunum may present as diffuse foci of intestinal obstruction due to early metastases to the peritoneum, as ascites, or as a malabsorption syndrome.

Argentaffine tumors are found in 0.5 per cent of all surgically removed appendices, as a yellowish

indurated area. They are the commonest epithelial tumors of the small intestine, and may appear anywhere from the duodenum to the colon. They arise from argentaffin cells in the crypts of Lieberkühn, and grow as clumps or strands of small closely packed polyhedral cells. The degree to which these tumors are regarded as malignant varies among pathologists, but there is increasing recognition of their invasive tendencies. They are often multiple, but when solitary some 60 per cent arise in the ileum, enlarging to form plaques projecting into the muscularis and serosa. Adenofibrosis of the surrounding tissues accompanies this spread so that ulceration from the luminal spread and compromise of the lumen by pressure of the inflammatory reaction may produce the symptoms. They are tumors of middle age, more common in men. Remote spread is infrequent and late. For some reason, lesions of the duodenum tend less to invade surrounding tissues. When metastases invade the liver, a characteristic syndrome results (see Chap. 80).

Lymphosarcoma, which may develop in any region where lymphoid tissue is present, is an important invader of the small intestine. Reticulum cell sarcoma usually develops in retroperitoneal lymph nodes, secondarily involving the bowel, localized lymphosarcoma usually involves the ileum as a solid bulky tumor which may cause fecal obstruction. It may remain stationary for a long time and can produce an x-ray picture simulating that of localized ileitis. When it spreads, it does so slowly, to regional lymph nodes. Hodgkin's granuloma and sarcoma may invade any organ in the body, but they rarely cause localized lesions in the small intestine. Enlarged retroperitoneal nodes may distort the x-ray picture of the upper small intestine, but localized infiltrations are uncommon.

Both *liposarcoma* and *leiomyosarcomas* are infrequently encountered in the small intestine. The symptoms may be the same as those of the benign tumors or of any malignant lesion.

Diagnosis. Tumors of the small intestine should be thought of in the differential diagnosis of obstructive syndromes of any type, of gastrointestinal bleeding, and of malabsorptive states. They are less likely to cause fever than is regional enteritis or tuberculosis, but in all other respects benign inflammatory disease, benign tumors, and malignant tumors of this organ can produce identical clinical syndromes. The reason for this is not hard to find, since most symptoms are due to: (1) ulceration of mucosa with bleeding; (2) obstruction of the lumen behind which mucosal bowel wall contracts forcibly, giving rise to crampy pain; (3) necrosis and inflammation of the wall, giving rise to persistent pain and tender masses; (4) interference with intraluminal, mucosal, and lymphatic aspects of digestion and absorption of nutrients.

producing abnormal stools, weight loss, anorexia, vomiting, and occasionally intestinal obstruction.

Radiologic techniques designed to differentiate localized from generalized lesions, pressure of enlarged nodes or inflammatory abscesses on the intestines, "deficiency patterns" and flocculation of barium in the bowel lumen, distortion of outlines of the bowel by stiffened mesentery—all these may be of the greatest diagnostic assistance, or may indicate only in a general way the nature of the underlying disease.

Localization of a specific bleeding point may be carried out by use of the long intestinal tube, through which luminal contents are aspirated and tested for blood, or by the use of a string test; in the latter maneuver, injection of fluorescein intravenously during active bleeding will stain the string at the site of bleeding; fluorescence of the stained area is proof positive of locus of bleeding.

Careful microscopic and chemical testing of the stools may confirm the presence or absence of an inflammatory exudate, cancer cells, and malabsorbed or maldigested foodstuffs, as well as blood, abnormal concretions, or parasites.

If a diagnosis of tumor is made presumptively or if symptoms persist and no diagnosis can be arrived at, laparotomy is indicated. Therapy for most of the tumors described is entirely surgical. In the case of lymphoma and lymphosarcomas, local removal and general radiation or chemotherapy are employed.

276 ACUTE INTESTINAL OBSTRUCTION

Albert I. Mendeloff and
Arnold M. Seligman

Definition. Acute intestinal obstruction may be defined as a failure of progression of intestinal con-

tents, whether due to mechanical causes or to inadequacy of intestinal muscular activity.

Etiology. The most useful classification is based on the immediate need for surgical or medical therapy. The *mechanical type* of intestinal obstruction usually requires surgical intervention for its correction. This type is due either to intraluminal obstruction by foreign bodies, gallstones, meconium, bezoars, enteroliths, and worms; or to mural obstruction due to encroachment by compression of the intestinal wall, such as in adhesions, stenosis, hernia, volvulus, intussusception, tumors, and atresia. *Nonmechanical obstruction* is referred to as *ileus*. Ileus is either adynamic (paralytic) or dynamic (spastic).

Adynamic ileus occurs (1) reflexly after certain surgical manipulations, diagnostic studies such as retrograde pyelography, or trauma; (2) secondary to peritoneal insult by chemical agents (hydrochloric acid or blood), pancreatic enzymes or bacterial agents; (3) as the result of metabolic changes, secondary to generalized dislocation of electrolyte equilibrium, especially abnormally low serum potassium levels, interference with the enzymes and coenzymes involved in acetylcholine synthesis (pantothenic acid), or due to drug effects (especially ganglionic blocking agents); (4) following mechanical *hypoactivity* in which the musculature of the intestinal wall loses its functional integrity on the basis of localized hypoxia secondary to compromised blood supply. This can happen suddenly as a result of arterial spasm secondary to venous or arterial thrombosis or embolism of intestinal vasculature, or more slowly when obstructing factors progress to a degree that embarrasses the arterial or venous blood flow through localized portions of the bowel.

Spastic ileus is an uncommon form of mechanical *hyperactivity* of the normal bowel behind a spastic segment or segments of the gut. It is seen in toxic conditions such as uremia, heavy metal poisoning, porphyria, infections, and extensive ulcerations.

Untreated ileus with progressive distention enhances mechanical obstruction as well as circulatory embarrassment in the wall of the involved lumen. In this way partial mechanical occlusion may progress to complete obstruction and eventually strangulation.

Symptoms. Acute mechanical intestinal obstruction is characterized by colicky pain, nausea, vomiting, distention, and constipation or obstipation. Obstruction high in the intestinal tract produces earlier and more severe vomiting, whereas obstruction low in the intestinal tract produces earlier obstipation, more distention, and later vomiting. When obstruction is accompanied by strangulation, the pain is more severe and constant, and the patient soon develops evidence of sepsis. Diagnosis

of the strangulation is relatively easy when a large segment of bowel is involved, but the diagnosis of devitalized bowel, although equally important, is difficult when only a few centimeters of bowel are involved. When the obstruction is primarily due to adynamic ileus, pain is absent, obstipation is present, and discomfort results when distention is severe enough to cause a tight abdomen, at which time tachypnea, tachycardia, and oliguria are the result of pooling of fluids in the intestinal lumen.

Pain in acute mechanical obstruction of the small bowel is referred to the midabdomen and occurs in severe paroxysms that reach a crescendo and cease abruptly. In acute mechanical obstruction of the large bowel, colicky pain is less severe and is referred to the lower abdomen. When the ileocecal valve is competent, distention is confined to the colon and vomiting occurs late if at all. As distention progresses, the intensity of the pain decreases and the paroxysms become less frequent. When strangulation supervenes, the discomfort becomes constant and pain becomes more localized to the quadrant of the abdomen in which the strangulated loop of bowel resides.

Vomiting occurs earlier and is more severe, the higher the obstruction in the intestinal tract. High obstructions result in earlier dehydration and alkalosis due to loss of hydrochloric acid, whereas lower obstructions result in slower dehydration, loss of alkaline fluid, and produce acidosis. Vomitus at first contains bile and mucus, but later becomes brown and fecal in odor because of putrefaction of protein in the small bowel. When the ileocecal valve is competent, little or no vomiting occurs in colonic obstruction.

Obstipation results in all cases of complete obstruction after the intestinal tract distal to the obstruction is emptied. In high obstruction, the lower bowel may function quite well for a time, e.g., expelling an enema readily, whereas in low intestinal obstruction and colonic obstruction obstipation occurs early. Blood in the scanty stool suggests strangulation in low lesions. Diarrhea is not encountered, except in those rare situations where mechanical obstruction is precipitated by gastroenteritis in already mechanically embarrassed loops of intestine. When the onset of constipation is gradual but steadily increasing in severity, chronic intestinal obstruction due to encroachment on the lumen of bowel by the growth of neoplasm should be suspected. The progression of symptoms may be marked by bouts of obstipation, distention, and cramps, only to be relieved by purgation with the passage of a fecal impaction. Eventually these measures fail to give relief and complete obstruction supervenes, with the added hazard of perforation into the peritoneal cavity of bowel proximal to the obstruction.

Physical Findings. The physical findings vary from very little at the onset, to severe dehydration and alkalosis or acidosis from continued vomiting, to localized or generalized distention with abdominal tenderness after several hours of obstruction. Severe sepsis and shock revealed by pallor, sweating, cold and clammy extremities, rapid pulse, hypotension, and stupor supervene when strangulation and perforation occur. Disorientation may be one of the earliest evidences of peritonitis, especially in older persons, occurring before shock becomes manifest. Clinical evidences of shock indicate extensive fluid and blood loss into bowel lumen, bowel wall, and peritoneal cavity as well as loss of fluid by vomiting. Shock is seen early when the intestine is infarcted, whether due to vascular occlusion or strangulation of bowel wall. Involuntary spasm of the abdominal muscles is noted only when strangulation with local peritonitis occurs and is not a prominent feature of acute obstruction. During paroxysmal painful contractions of small intestine, proximal to the point of obstruction, there is noted voluntary rigidity of the abdominal wall, but this subsides when the contraction subsides. These paroxysms of bowel contraction are accompanied by auscultatory sounds that are exaggerated, gurgle more than normal due to the abnormal amounts of fluid in the bowel, and become more high pitched as gaseous distention increases. Sometimes one can locate the noisy proximal bowel in one quadrant of the abdomen by auscultation with a stethoscope. The sounds become more tinkling in character as the ileus progresses, and the abdomen is silent when ileus becomes adynamic, such as occurs when peritonitis is superimposed or when large segments of bowel are infarcted.

Distention in high obstruction may be limited to the upper abdomen and in low colonic obstruction may outline the colon. Most of the gas in the distention that accompanies acute intestinal obstruction is from swallowed air. In those who tend to swallow air readily and unconsciously, gaseous distention may develop very rapidly indeed and to a degree not only to aggravate mechanical obstruction but to endanger life by respiratory embarrassment, cardiac arrhythmias, and the precipitation of vascular insufficiency of the gut with perforation. When perforation results, it usually occurs on the antimesenteric surface.

Detection of a large heart with irregular rhythm, or the definitive finding of mitral stenosis, may suggest that an embolus to the superior mesenteric artery has occurred. Embolism to that artery is also rendered possible by a history of recent myocardial infarction, subacute bacterial endocarditis, or other embolic phenomena. In an older patient, palpation of an abdominal aortic aneurysm, evidence of defective arterial circulation to the legs.

or history of diffuse abdominal pain exacerbated by eating all suggest diffuse aortic arteriosclerosis with entrapment on the lamina of vessels supplying the intestine. Rarely, periarteritis nodosa will cause thrombosis of the superior mesenteric artery or one of its branches. When portal hypertension is present, thrombosis of the portal venous bed may occur, with resultant mesenteric venous thrombosis. Polycythemia vera, postsplenectomy states, and disorders of the coagulating mechanism such as thrombotic thrombocytopenic purpura are rare but documented causes of venous mesenteric thrombosis.

Roentgenographic Findings. An x-ray is a very valuable adjunct to the physical examination in demonstrating whether gas is present in loops of small bowel with or without fluid levels, whether gas is in the upper or entire small bowel, or in single loops of intestine, or primarily in the colon. A clue to the point of obstruction may be obtained often by a flat film together with a film of the patient sitting up or lying on his side. Classical radiologic evidence of obstruction of the small intestine is seen in Fig. 276-1, the stepladder distribution of distended small bowel loops being readily identified. Distention of the large bowel is usually recognized on the flat films from the distribution of the air-filled colon, the haustral markings extending not entirely down the lumen. Volvulus of the sigmoid colon presents a very characteristic radiologic picture, and various forms of internal or sliding hernias give characteristic radiologic patterns. The diagnosis may be much more difficult when low-grade or early obstruction is present or when large fecal masses obscure the picture. In acute obstructions it is not wise to give barium by mouth, although in chronic situations contrast media can sometimes be injected through a tube in the intestinal tract to visualize the point of obstruction. If evidence points to colonic obstruction, a carefully administered barium enema will often demonstrate the point of obstruction and reveal its cause.

Laboratory Findings. Laboratory findings are usually related to the amount of necrosis, the presence of peritonitis, and other chronic diseases which may underlie the catastrophe. Leukocytosis is usually of moderate degree, the hematocrit may be high, and electrolytes are disturbed to various degrees. Lactic dehydrogenase levels in the serum are often very high in intestinal infarction. The stool may be grossly bloody if a large area of small bowel has been infarcted.

Treatment. Therapy consists in (1) correcting fluid and electrolyte imbalance, (2) alleviating vomiting and distention by intubation and decompression, (3) control of peritonitis if present and blood transfusion for shock if present, and (4)

FIG. 276-1. Paralytic ileus due to thrombosis of superior mesenteric artery.

removal of the obstruction and restoration of bowel continuity and function.

Since the efflux of fluid into the dilated gut and peritoneal cavity results in dehydration and often hemoconcentration, and since chloride is lost in high obstructions, and both sodium chloride and potassium chloride in lower obstructions, the administration of saline and potassium chloride is indicated. Extra water should also be given in the form of 5 per cent glucose. Because these patients have not taken anything by mouth and will continue not to do so for several days, caloric requirements (2,000 per day) must be met by continuous infusion of glucose and parenteral vitamin preparations should be given. Adequate hydration can be gauged by measuring urinary excretion, which should be kept near a liter per day. The hematocrit is also useful in determining the results of combating hemoconcentration. Determination of sodium, chloride, potassium, and bicarbonate ionic levels in the serum twice a day in very sick patients serves as a useful guide to electrolyte therapy and control of acidosis or alkalosis. No attempt to maintain nitrogen equilibrium other than by blood and plasma infusion is indicated in short periods of disability.

277 ACUTE APPENDICITIS

Albert I. Mendeloff and
Arnold M. Seligman

Decompression is best achieved by intubation with one of the long, weighted intestinal tubes attached to gentle continuous suction. Single lumen tubes drain more effectively than double lumen tubes. This method of decompression, supplemented with pantothenic acid parenterally, is useful in adynamic ileus. However, there is great danger in relying solely on this means of relieving mechanical obstruction whenever there is any question of strangulation of bowel or when large bowel obstruction occurs in the presence of a competent ileocecal valve. Early operative intervention is required in all such cases.

In the majority of cases, surgical intervention is necessary to remove the obstructing agent and restore normal bowel continuity and function. In some cases due to adhesions and hernia, relief by decompression suffices, and in some cases of intussusception or volvulus, a barium enema under fluoroscopy restores normal continuity. Many cases of adynamic ileus are cured by tube decompression alone. However, if the patient does not improve rapidly on such conservative measures, operation within 24 hr is indicated to establish an accurate evaluation of the cause of obstruction and to effect a cure. When severe distention is not relieved promptly by intubation, surgical intervention is required for immediate decompression by means of enterostomy or colostomy. However, treatment of shock and dehydration should be instituted before surgery is undertaken in order to lessen the operative risk.

Prognosis. The prognosis is always guarded, depending upon the level of obstruction, being poorer in high obstruction than in low intestinal obstruction, and upon the viability of the bowel wall, the length of time the bowel has been obstructed and strangulated, and the amount of bowel involved in the strangulation. Patients with complicating peritonitis from perforation have a poor prognosis, and this is especially true in very young infants or in elderly patients with complicating cardiovascular or renal disease.

Inflammation of the vermiform appendix constitutes one of the commonest and most important acute disease processes. Although descriptions of isolated cases of the disease had been written in the seventeenth and eighteenth centuries, and appendiceal abscesses had been described at autopsy, it was Reginald Fitz in 1886 who first collected a series of cases in which clinicopathologic correlations were established.

Epidemiology. The disease occurs in all age groups, but appears to be productive of higher mortality rates in the group aged five to fourteen and after age fifty-five. It is estimated that in 1916, in England and Wales, one case occurred every year for every 700 of the population. The incidence of the disease is somewhat higher in males, and the death rates for the period prior to 1916 were 40 per cent higher in males. A consistent feature of the disease has been its greater incidence and mortality in the upper socioeconomic stratum and its tendency to decline in frequency during periods of food shortages. In Western Europe and in the United States, the death rates for the disease have shown a steady decline, ranging from 81 per 100,000 population in 1941 to 1.3 per 100,000 in 1956. There is also definite evidence that the incidence of the disease has recently decreased, despite great increases in the number of admissions of surgical patients to American hospitals since the Second World War, the absolute number of acutely inflamed appendixes removed has steadily declined by 30 to 60 per cent, and approximately at the same rates in urban and rural institutions. It is difficult to explain this decrease by single causation. Possible factors are the greater use of effective antibiotics and chemotherapeutic agents to treat upper respiratory infections, some of which undoubtedly have been associated with appendicitis, and a lessened infestation with helminths. Changes in diet have also occurred, changes which many feel have increased the incidence of degenerative disease, but may have sharply reduced the incidence and the mortality from appendicitis. Surgeons are also probably more careful about removing nearly normal appendixes now than heretofore. None of these explanations is adequate to clarify in its totality what appears to be a progressive and definite decrease in the incidence of one of our most important acute inflammatory diseases.

Pathogenesis. Appendicitis is an inflammation of the vermiform appendix involving all layers of the organ, beginning either as a focal ulceration or as a diffuse phlegmon. Evidence of a focal point of

obstruction due to fecalith or stricture is sometimes found. The appendiceal artery is an end artery, and its tributaries are susceptible to occlusion from the increased pressure within the lumen of the obstructed appendix or direct pressure of a fecalith. Infections lead to vascular thrombosis, local necrosis, and infarction resulting in perforation. Streptococcal involvement, which rises in frequency when acute respiratory infections are prevalent, adds to the necrotic process and to the virulence of the disease. The process either subsides early or progresses to gangrene or perforation with abscess or peritonitis. Chronic inflammation occurs only with the granulomatous infections such as tuberculosis, amebas, or actinomycosis. Recurring appendicitis due to spontaneous subsidence of acute attacks should not be considered chronic appendicitis. Recognition of the disease as an entity was first made by Fitz, and treatment by appendectomy was introduced thereafter by Morton, Ochsner, Murphy, McBurney, and Deaver. Since then to the present time, acute appendicitis is the most common major surgical disease.
